Plant macrofossils and pollen play complementary roles in paleoecology. Each has its own advantages and shortcomings. Used separately, they provide valuable information about past vegetation. Used together, the two types of data can corroborate or, occasionally, challenge each other, and they can provide more detailed and refined understanding of past vegetation at multiple spatial scales. In this article, we briefly compare and contrast the flora- and vegetation-sensing properties of pollen and macrofossil data and then present a series of case studies in which the two data sets have been used together profitably at spatial scales ranging from local to continental. We focus on macrofossils from ‘wet’ sediments (lakes, peatlands, buried soils, fluvial deposits, etc.) and do not explicitly treat macrofossils from rodent middens and archaeological sites.

Vegetation-Sensing Properties of Pollen and Plant Macrofossil Data

Pollen grains comprise a distinct and uniform stage in the life history of seed plants—the gametophyte generation. Pollen grains are small, with a restricted range of sizes (5–150 μm), and most are packaged in sporopollenin, a refractory organic compound. Plant macrofossils from seed plants represent the sporophyte generation. However, because seed plant sporophytes are multicellular, differentiated entities, plant macrofossils can take any of a variety of forms: seeds, fruits, anthers, microsporangia, megaspores, ovulate cones, leaves, needles, petioles, bud scales, buds, twigs, branches, etc. The size range is potentially vast, from seeds $<1\text{ mm}^3$ to buried trees $>20\text{ m}^3$. Materials are also variable, although macrofossils preserved in sediments tend to be composed of the more refractory compounds (particularly cellulose and lignins).

Pollen grains are typically morphologically invariant among species within most anemophilous genera and among many genera within certain families. In contrast, interspecific morphological variation of sporophyte plant organs is typically large since plant species are generally described and distinguished based on sporophyte morphology. Accordingly, many plant macrofossils can be identified to species, in contrast to the corresponding pollen grains. This imparts one of the three unique features of plant macrofossil data compared to pollen: high taxonomic resolution. Macrofossils allow us to surmount the taxonomic smoothing frequently imposed by pollen data.

The second unique feature of plant macrofossils is their local nature. Plant macrofossils generally do not travel far when airborne; the primary mode of transport beyond 10^1 – 10^2 m is by surface waters or animals. For depositional basins with no inflowing streams, most plant macrofossils

derive from within 10^1 – 10^2 m of the shore. For depositional environments with a fluvial component, macrofossils must have been derived from plants growing somewhere within the catchment above the point of deposition. In contrast, pollen grains can be transported by wind for distances up to 10^4 km , although more typical travel distances are on the order of 10^1 – 10^5 m . Pollen assemblages in a lake or wetland basin represent a distance-weighted integration of vegetation surrounding the basin, with significant representation of distant vegetation (i.e., $>10^3\text{ m}$). In contrast, plant macrofossils provide a more-local sampling of vegetation, undoubtedly distance-weighted, but with little or no representation beyond ca. 10^2 m (Table 1).

Many plant taxa are poorly represented in pollen assemblages due to low productivity, poor dispersal, poor preservation, or adaptations for zoophilous transport. Many of these taxa—*Pseudotsuga*, *Larix*, *Abies*, *Dryas*, *Populus*, *Oxyria*, *Polygonum*, and *Nymphaeaceae*—are well represented in plant macrofossil assemblages from lakes and other depositional environments. Thus, plant macrofossils can provide information about taxa for which the pollen record may be unreliable—the third unique feature of macrofossil data. This complementarity does not hold for all taxa, however; some plants are poorly represented in both pollen and macrofossil assemblages. For example, *Liriodendron*, an important tree species of eastern North America, is entomophilous and hence almost completely absent from pollen records, regardless of local or regional abundance. Fruits, bud scales, and leaves of *Liriodendron* are large and poorly dispersed, and hence show up only rarely in macrofossil assemblages. Some taxa well represented in pollen assemblages (e.g., *Quercus*, *Carya*, and *Corylus*) are poorly represented as macrofossils in many depositional settings.

Macrofossil and Pollen Representation Within and Among Depositional Environments

Representation of plant macrofossils is far more subject to influences of site type and local depositional environment than pollen. Pollen grains may be subjected to some secondary sorting by fluvial transport and sediment focusing. However, pollen assemblages from diverse depositional environments (lakes, wetlands, forest-floor moss polsters, soil samples, alluvium, caves, and rodent middens) are generally similar within a region due to widespread airborne transport and mixing prior to deposition. In contrast, macrofossils are not subject to the same degree of mixing due to large size and poor dispersal. Furthermore, macrofossils are more subject to sorting by airborne and fluvial dispersal processes than pollen (Spicer, 1989; Greenwood, 1991).

Lakes

Lake sediments are generally the most widely used sources of both pollen and plant macrofossil data. Within-lake variation in pollen assemblages is significant, but the variation is generally small relative to variation among lakes. In contrast, plant macrofossil assemblages within a single lake vary substantially, depending on water depth, distance from shore, and vegetation composition on the nearest shore. Most macrofossil deposition to the water surface will occur close to shore, whereas the best environment for macrofossil preservation in sediments will be in deep waters, which tend to be offshore (Watts, 1978). Moderate-sized lakes (5–100 ha) with relatively gentle bottom slopes will have few macrofossils preserved near shore, where influx is highest, because of high decomposition and low sediment accumulation rates. Deeper waters with good preservation and high sediment accumulation rates will also have few macrofossils because of poor offshore dispersal. Highest macrofossil concentrations will occur in intermediate depths, deep enough to preserve macrofossils and close enough to shore to ensure high macrofossil influx. Since most paleoecologists obtain cores from the deepest portions of lakes, it should come as no surprise that macrofossils are often absent or rare in sediment cores.

Significant sorting of macrofossils occurs with distance from shore due to differential dispersal (and, in some cases, flotation) properties of various plant organs. Large, coarse materials (large, gravity- or animal-dispersed seeds and fruits, ovulate cones, large leaves, branches, etc.) are rarely dispersed more than a few tens of meters from shore, where they are likely to sink and then decompose in shallow benthos. Smaller organs (small seeds and fruits, conifer needles, and bud scales) are dispersed farther from shore and hence are better represented in offshore sediments. In deep waters more than 100 m from shore, only small fragments of small-diameter conifer needles, papery bud scales, and small winged fruits (e.g., *Betula papyrifera* and *B. pubescens*) are typically present. The relative contributions to offshore deposition of airborne dispersal, flotation, and skating across winter ice are inadequately known.

Selection of coring sites for macrofossils thus represents a trade-off between maximizing macrofossil preservation (deep water) and deposition (near shore). For large lakes, it is advisable to run a transect of short cores or dredge samples to determine the ideal site for macrofossil deposition. Alternatively, careful selection of lakes can yield good macrofossil results. In particular, small or moderate-sized lakes with deep waters 10–50 m offshore and steep sides can have very high macrofossil concentrations, yielding excellent records of upland terrestrial vegetation.

Lake sediments are typically sampled using piston-corers with diameters ranging from 5 to 10 cm. Thus, sample volume is limited, and some plant organs of moderate size or intermediate dispersal properties (e.g., *Acer* samaras (one seeded, winged fruit), most deciduous leaves, and coarse conifer needles) are not reliably sampled: Absence from sediments cannot be attributed to absence from vegetation. However, other plant organs (winged seeds of *Betula*, *Alnus*, and many conifers, conifer needles, and many bud scales) are consistently represented in modern lake sediments (Figure 1) and between adjacent stratigraphic samples within a core (Figure 2). In such cases, absence from sediments can be inferred to indicate absence from or rarity in vegetation near the lakeshore. Careful selection of lakes and coring sites within lakes, together with use of large-diameter coring devices (7.5 or 10 cm), can yield records in which the presence/absence of macrofossils in the stratigraphic column can be applied directly to the presence/absence in adjacent vegetation. Also, as discussed later, macrofossil presence/absence and abundance patterns often show close stratigraphic correspondence to pollen abundance of the corresponding taxa.

Wetlands

Macrofossils in wetland sediments can provide excellent records of local wetland vegetation. Shallow water or subsurface water tables limit the extent of waterborne dispersal of macrofossils, and floating-leaved and emergent plants further reduce waterborne dispersal by providing a series of traps and baffles. This has the advantage of amplifying local representation of macrofossils, which can be used to examine local vegetational and hydrological dynamics within a wetland (Watts and Winter, 1966; Singer et al., 1996; McMullen et al., 2004). In fact, species richness of wetland/aquatic macrofossil assemblages can be very high in wetland sediments. In general, macrofossils from surrounding uplands are restricted to plant organs that are particularly well dispersed by airborne means (small samaras, winged seeds, bud scales, and some conifer needles). Sediments are usually sampled using coring devices, with the sample size limitations described previously for lakes. Wetlands with low sediment accumulation rates, oxygenated waters, and/or sustained drawdown periods can have sediments depauperate in macrofossils, as can humified bog peats.

Fluvial Sediments

Fluvial sediments have been underutilized as sources of plant macrofossil data. Concerns with fluvial transport and discontinuous deposition at individual sites have inhibited their use. However, fluvial deposits from low-order (i.e., headwater) streams restrict the potential source area for macrofossils, and

Figure 1 Scatter plots showing the relationship between the presence (P) and absence (A) of macrofossils in modern sediments of 22 lakes and abundance of trees within a 20- and 100-m radius of the lake margin. All sites are small lakes (0.1–2.0 ha) in the northeastern United States (New York, Rhode Island, Massachusetts, and Connecticut). Surface samples comprise 100–200 cm³ obtained using an Ekman dredge from the center of the lake. *Acer rubrum* macrofossils comprise samaras and leaves. *Betula papyrifera* macrofossils comprise samaras and catkin bracts. This taxon includes *B. populifolia* at several sites. Samaras and bracts of the two species are morphologically similar but distinguishable. Because the two species are closely related, have similar growth form, and their macrofossils have similar dispersal properties, we lumped them for purposes of this figure. *Picea* sp. macrofossils include needles, sterigmata (needle stems), seeds, microsporangia, and twigs. Species at the sites include *P. rubens* and *P. mariana*, which are closely related and morphologically indistinguishable for macrofossil types other than cones. *Acer rubrum* macrofossils are large and poorly dispersed relative to the other two species. The occurrence of *A. rubrum* macrofossils in sediment samples of this size (typical of sediment cores) is inconsistent. The absence of macrofossils cannot be construed as indicating the absence of nearby populations. Larger sediment samples might increase the probability of macrofossil occurrence. *Betula papyrifera* and *B. populifolia* macrofossils are small, abundantly produced, and well dispersed. Macrofossils are consistently represented in sediments even when local populations are very small. Some sites lacking any *B. papyrifera* or *B. populifolia* trees within 20 m of shore have macrofossils in sediments, dispersed from trees between 20 and 100 m from shore. *Picea* sp. macrofossils are also very well represented in sediments. In general, if small populations are present near shore, macrofossils are present in sediments. *Picea* trees produce a variety of small organs that are well dispersed and well preserved in sediments. In the case of both *Picea* and *B. papyrifera*, the absence of macrofossils in sediment samples of this size, in lakes of this size and morphometry, can be interpreted as indicating the absence or scarcity of nearby populations. Consistent absence among adjacent samples in a core can be construed to indicate the absence of nearby populations. Source: S. T. Jackson, unpublished data.

individual ‘snapshot’ assemblages can be dated and stacked. Fluvial deposits are usually collected from excavations or from streamcut exposures, and hence sample size is not limited by a coring device. Furthermore, fluvial transport and deposition can concentrate large plant organs (leaves, large seeds and fruits, branches, etc.) that are rare in sediments of most lakes. Significantly, the only macrofossil records of several North American trees (e.g., *Quercus*, *Juglans*, *Liriodendron*, and *Carya*) are from fluvial deposits. Paleoecologists occasionally turn to fluvial deposits in the absence of better sites. The exemplary studies of Richard Baker and colleagues in the Upper Mississippi River Valley indicate that macrofossil and pollen studies of fluvial deposits can potentially yield far richer records of upland vegetation change than lakes or wetlands. (see Holocene North America).

Other Depositional Settings

Plant macrofossils are also preserved in a variety of other depositional settings, ranging from glacial and glaciomarine to former land surfaces buried *in situ* with contemporary

vegetation. In most of these depositional settings, samples are collected from exposures, and sample size is not as limited as for cores. Buried *in situ* vegetation can provide a unique window on past community composition and population density, and accompanying pollen assemblages are comparable to samples from modern soils.

Data Expression

Quaternary pollen data are most commonly expressed as percentages of a defined pollen sum. Certainly, virtually all applications of Quaternary pollen data are quantitative; presence/absence applications are generally pre-Quaternary. Plant macrofossil data, by contrast, are more heterogeneous in expression. Data range from presence (anecdotal occurrences) to presence/absence to quantitative. Macrofossil data from sediment cores are typically presented as concentrations (number of specimens per unit volume of sediment) or, occasionally, accumulation rates (numbers deposited per unit area per year). These data can, of course, be reduced to presence/absence data.

Figure 2 Pollen and macrofossil sequences for *Betula* from two lakes in the Upper Peninsula of Michigan. Ackerman Lake (6 ha) is south of Munising Bay. Steep slopes on the south and east sides, near the coring site, are forested by *Tsuga canadensis*, *Acer saccharum*, *Betula alleghaniensis*, and *Fagus grandifolia*. Partridge Lake (3 ha) is situated near the tip of the Keweenaw Peninsula, 160 km northwest of Ackerman Lake. The steep slopes surrounding Partridge Lake are forested by *A. saccharum*, *B. alleghaniensis*, *Quercus rubra*, *Picea glauca*, and *Pinus strobus*. *Betula* pollen undergoes a dramatic late Holocene increase at both sites, but the increase at Ackerman Lake occurs approximately 1000 years before the increase at Partridge Lake. This would appear to represent a time-transgressive westward migration or expansion of *Betula*, but the pollen data alone render interpretation difficult. Plant macrofossil data clarify the interpretation: The pollen increase at both sites is coincident with first appearance of macrofossils of *B. alleghaniensis*, which persists in both records until the present. Thus, the pollen pattern represents westward expansion of *B. alleghaniensis* populations. *Betula papyrifera* was the sole or dominant *Betula* species before the *B. alleghaniensis* expansion, and it was associated with lower pollen percentages. *Betula papyrifera* is absent from Ackerman Lake sediments after the *B. alleghaniensis* invasion. This probably represents a climate-driven change in disturbance regime rather than competition; *B. papyrifera* regeneration is dependent on large-scale, stand-replacing disturbances (crownfire and extensive windthrow). *Betula papyrifera* persists at Partridge Lake throughout the late Holocene, co-occurring with *B. alleghaniensis*. Stand-replacing disturbances (particularly crownfires) were probably more prevalent near Partridge in the late Holocene; this is consistent with continued high percentages of *Pinus* pollen. Modified (with updating) from Jackson ST and Booth RK (2002) The role of late Holocene climate variability in the expansion of yellow birch in the western Great Lakes region. *Diversity and Distributions* 8: 275–284.

Stratigraphic changes in macrofossil concentrations within a sediment core are generally interpreted as indicating changes in species abundance and vegetation composition. Such interpretations assume that the depositional setting has remained constant. This assumption can be violated in particular if water level changes in the basin have resulted in changes in the preservation environment, distance from the source vegetation along the lakeshore, or density of intervening emergent and aquatic vegetation. However, coring of small deep lakes, or of deep water close to shore, can ensure that this assumption is justified.

Greater difficulties are encountered in comparing assemblages between cores within a lake, or particularly among lakes. Differences in pollen percentages among lakes can be attributed in large part to vegetational differences, whereas differences in pollen concentrations may be attributable to

differences in depositional setting or other factors. Macrofossil concentrations can be compared among lakes along environmental transects, and such comparisons often give sensible results in terms of vegetational patterns. However, such comparisons should be standardized carefully for morphometric and other variables such as distance from shore. Alternatively, a macrofossil sum can be designated and used to calculate macrofossil percentages (Watts and Winter, 1966; Tinner and Kaltenrieder, 2005), facilitating between-site comparison (Jackson and Whitehead, 1991).

For broader comparisons, particularly among different site types, any quantitative expression poses an “apples and oranges” problem, so data are generally reduced to presence/absence. For plant taxa that are particularly well represented in macrofossil assemblages, mapped presence/absence of modern macrofossils closely approximates modern geographic

distributions, and hence snapshot maps of past time intervals can be used to map range dynamics of these species (Jackson et al., 1997).

Tandem Applications of Pollen and Plant Macrofossil Data

Macrofossil and Pollen Data from Individual Sites

Innumerable studies comparing pollen and macrofossil stratigraphy from individual sediment cores have been published, and records of the same taxa generally show parallel stratigraphic changes in abundance. In these cases, the pollen and macrofossils provide mutual corroboration. The two data types are subject to completely different taphonomic processes and record surrounding vegetation at vastly different spatial scales. The fact that pollen and macrofossils of the same taxa so often track each other temporally gives us confidence that both data sets are tracking changes in upland vegetation.

Macrofossils provide far more than corroboration of pollen data, and vice versa: The differential taphonomic biases, differential spatial integration, and differential taxonomic resolution can be used in complementary ways to refine our interpretations of past flora, vegetation, and environment. We provide a few representative examples here.

Tandem studies of pollen and plant macrofossil analyses from the same sites are being used to study late Holocene dynamics of birch species in the western Great Lakes region. Pollen records from the region document increasing birch (*Betula*) pollen in the late Holocene. However, two species of birch trees (*B. papyrifera* and *B. alleghaniensis*) with morphologically similar pollen grains occur in the region, hampering detailed ecological and climatic inferences from the birch pollen record. Both species produce morphologically distinct, highly dispersible samaras and catkin bracts in large numbers. These macrofossils are well represented in sediments of lakes and small peatlands in the region. Detailed studies of pollen and macrofossils from lake sediment cores indicate that *B. papyrifera* has been an important component of regional upland vegetation throughout the Holocene, and that *B. alleghaniensis* has migrated into the region only during the past 4500 years (Figure 2). This latter migration resulted in a time-transgressive increase in *Betula* pollen percentages from east to west across the region (Jackson and Booth, 2002). Similar integrated studies of pollen and macrofossils have helped refine interpretation of pollen records from numerous other regions. The increased taxonomic precision imparted by macrofossil records coupled with the regional smoothing of pollen records can lead to detailed reconstructions of vegetation dynamics that could not have been inferred using either method independently.

An extreme example of how the increased taxonomic resolution of macrofossils can alter interpretations of pollen assemblages comes from an extinct species, *Picea critchfieldii* (Jackson and Weng, 1999). Pollen assemblages from much of the unglaciated southeastern United States show high percentages of *Picea* pollen, routinely ascribed to the boreal and montane *Picea* species that grow in eastern North America today. *Picea* macrofossils found at many of these sites corroborated this interpretation, which, together with other evidence, led to

the perception of widespread boreal forest or mixed boreal conifers/cool-temperate hardwoods at low latitudes (to 30° N) with accompanying drastically reduced temperatures. More detailed morphological and anatomical studies of the *Picea* cones and needles, respectively, led to the discovery that an extinct species, *P. critchfieldii*, occurred over much of the region and was the only *Picea* species at some sites (Jackson and Weng, 1999). This has led to reevaluation of the Pleistocene biogeography, paleoecology, and paleoclimatology of the entire region (Jackson et al., 2000). Whether the pre-Holocene demise of *P. critchfieldii* is one of many plant extinctions or a singular occurrence remains obscure. However, Pleistocene macrofossils of other taxa should be scrutinized to determine whether they belong to extant species.

Macrofossils are also important in detecting palynologically cryptic populations or taxa. Obvious examples include the taxa that are poorly represented by pollen in modern assemblages due to low productivity, poor dispersal, or rapid decomposition (e.g., *Larix*, *Pseudotsuga*, and *Populus*). However, macrofossil data reveal that pollen assemblages, by virtue of their wide spatial integration, may miss important aspects of vegetation and flora. This has become particularly obvious in glacial-age and late-glacial settings (Jackson et al., 2000; Willis et al., 2000; Jackson and Williams, 2004; Willis and Van Andel, 2004). Pollen data for the last glacial period in Europe indicate extensive treeless vegetation; low representation of arboreal pollen types suggests the absence of trees anywhere north of the southern Balkans and Iberian and Italian peninsulas (Huntley et al., 2003). However, charcoal of woody plants (*Picea*, *Pinus*, and *Betula*) has been found in glacial-age paleosols and archaeological sites in central Europe (Willis et al., 2000; Willis and Van Andel, 2004). Similarly, macrofossils of *Pinus strobus*, *B. papyrifera*, *Fagus grandifolia*, *Quercus* spp., and *Carpinus caroliniana* occur in glacial-age sediments of the unglaciated southeastern United States, even though pollen is absent or occurs in trace amounts at the same sites (Jackson et al., 2000). All of these taxa, both European and North American, are prolific pollen producers that are well represented in modern pollen assemblages. Their poor representation in the Pleistocene assemblages remains enigmatic, potentially attributable to their occurrence in small, scattered populations (e.g., in locally wet sites) or to differential effects of reduced CO₂ on physiognomy and reproductive allocation (Jackson and Williams, 2004). Phylogeographic evidence, particularly from North America, suggests that glacial-age populations of temperate trees may have been substantially farther north than suggested by pollen records (McLachlan et al., 2005).

The apparent discrepancies between glacial-age records of pollen and macrofossils arise in part from the vast differences in spatial integration and source area of the respective data types. These differences have manifestations in the Holocene as well and can be used to tease apart scale-dependent patterns in the paleoecological record. We discuss some examples in the following sections that involve spatial arrays or synoptic networks of sites. Here, we discuss a few site-based case studies from the Holocene. Pollen data are effective in indicating population changes, including invasion/expansion, integrated over a large area. The efficacy of pollen data in detecting small, scattered colonizing populations has been the subject of considerable discussion (McLachlan and Clark, 2004).

Comparison of Holocene pollen and macrofossil records indicates that pollen data are in many (and perhaps most) cases ineffective at determining the timing of colonization. Macrofossil occurrences have been observed to precede increases in pollen percentages beyond trace levels by hundreds or thousands of years (Peteet, 1991). Peteet's study, together with the glacial-age anomalies discussed previously, indicates that small, scattered populations of tree species can go undetected in pollen records—an observation consistent with what is currently known about pollen dispersal and representation.

Because of long-distance pollen dispersal, plant macrofossil occurrences seldom precede high pollen percentages in migrating populations. For example, in the Adirondack Mountains of New York, *Pinus strobus* pollen percentages increased at least several hundred years before *Pinus strobus* macrofossils first appeared in sediments (Jackson and Whitehead, 1991). However, in northern Michigan, the first occurrence of *P. strobus* macrofossils in lakes is synchronous with the first occurrence of pollen beyond trace amounts (Booth et al., 2004). The difference may stem from the occurrence of extensive lowlands surrounding the Adirondack highlands, which may have fostered extensive *P. strobus* populations before the species migrated upslope.

Macrofossils can also indicate leads and lags in local population response during periods of decline. Macrofossil and pollen data reveal, for example, that as prairie expanded to replace mesic forest in uplands of southeastern Minnesota during the mid-Holocene, local populations of *Ulmus* persisted on floodplains for at least 500 years after the regional shift (Baker et al., 2002). This may represent persistence of one or two tree generations on the more favorable floodplain sites or gradual climate change that passed thresholds for forest growth on uplands first and wetter sites later. If local populations persist, they become 'relict' populations, and their development can be observed by comparing pollen and macrofossil data from individual sites (Watts, 1979) and in mapped networks (Figure 3).

Differences in the source area of pollen and macrofossil records also have enabled comparative investigations of the dynamics of wetland and upland systems. For example, by comparing the timing of changes in pollen derived from upland trees and changes in the concentrations of locally deposited wetland plant macrofossils, several studies have assessed the relative importance of climatic versus autogenic controls on peatland development and dynamics (Singer et al., 1996; Campbell et al., 1997; Booth et al., 2004).

Figure 3 Mapped patterns of macrofossil presence/absence (top) and pollen percentages (bottom) of *Picea* in eastern North America since the Last Glacial Maximum. Open and closed circles in the top map respectively represent the absence and presence of *Picea* macrofossils at sites corresponding to the respective time periods. Time windows for the mapping are broad, encompassing approximately 1000 years for the Holocene (10 ka, 6 ka, and the present), 2000 years for the Late Glacial (14 ka), and 3000 years for the Last Glacial Maximum (21 ka). Comparison of the maps shows general correspondence between pollen and macrofossils. Disappearance of macrofossils from some individual sites lags behind pollen declines during the northward retreat of the southern range limit of *Picea* in the Late Glacial and early Holocene. Local *Picea* populations occurred across a wide swath south of the ice margin during the early Holocene (10 ka), despite the poor representation of pollen in sediments of this period. These patterns probably arise from the persistence of local *Picea* populations in favorable sites (e.g., in wetlands and along lake margins) after regional, upland populations had declined. Modified from Jackson ST, Overpeck JT, Webb T III, Keatts SE, and Anderson KH (1997) Mapped plant macrofossil and pollen records of Late Quaternary vegetation change in eastern North America. *Quaternary Science Reviews* 16: 1–70; and Jackson ST, Webb RS, Anderson KH, et al. (2000) Vegetation and environment in unglaciated eastern North America during the Last Glacial Maximum. *Quaternary Science Reviews* 19: 489–508.

Regional Studies: Site Transects and Networks

Plant macrofossils and pollen have been used together in a number of regional studies, nearly all involving elevational gradients. In typical montane regions, most of the land surface is at low elevations, and frequently the highest pollen productivity is in low-elevation vegetation (e.g., forests). Widespread pollen dispersal tends to smooth vegetational patterns along elevational gradients, and discrimination of elevation-specific vegetation composition and elevational boundaries of individual species and forest types is difficult. Site transects using both pollen and plant macrofossil data have led to elevationally precise reconstructions of vegetation patterns and species ranges (Table 2). Intersite comparisons impose challenges of macrofossil data expression. Montane studies have variously used presence/absence, concentrations in sediments, and macrofossil percentages based on a defined sum (Table 2). In general, these studies confirm the differential spatial smoothing of pollen and macrofossil data, with the macrofossils providing spatially detailed records of vegetation composition and species ranges.

Macrofossils have not been used as extensively in regional studies focused on landscape patterns (e.g., edaphic mosaics) or geographic gradients (e.g., studies of species invasions). Macrofossils from packrat middens show the potential power of these kinds of studies (Betancourt et al., 1990; Lyford et al., 2003), and similar study designs should be developed using

macrofossils from lakes and other sites (Peñalba and Payette, 1997). (see Rodent Middens).

Synoptic-Scale Studies: Mapped Networks

Synoptic-scale studies utilizing pollen data have been a tradition in Quaternary ecology since the pioneering work of Szafer and Sears, and mapping of pollen data at regional to continental scales is now routine (Williams et al., 2004). Plant macrofossils, in contrast, have not been widely applied in synoptic-scale studies. One of the challenges in doing so, of course, is determining data expression. Presence/absence has worked well in recent applications, and the most comprehensive applications to date have been in eastern North America (Jackson et al., 1997, 2000). These studies show generally corresponding patterns between pollen and macrofossil data (Figure 3). For several taxa (e.g., *Pinus*, *Picea*, and *Betula*), the higher taxonomic resolution of the macrofossil data clarifies interpretational uncertainties in the pollen mapping. Also, the maps reveal patterns of occurrence of taxa that are cryptic in the pollen record, particularly for the Last Glacial Maximum. These studies of a select number of taxa provide an indication of the potential power of systematic comparison of mapped patterns of pollen and macrofossil data.

Other mapping efforts involving pollen and macrofossil data include those by Tarasov et al. (1998), Gunin et al. (1999), McLachlan and Clark (2004), and Edwards et al. (2005). The latter study shows how pollen and macrofossils can give contrasting and complementary views of regional vegetation composition and physiognomy.

Future Prospects

Plant macrofossils can serve as equal or even superior partners with pollen data in many contexts and for many questions. However, despite widespread application in Quaternary paleoecology and paleoclimatology, plant macrofossils continue to play a subservient role to pollen in most studies. The primary exceptions are fossil rodent middens and some studies of fluvial deposits, ombrotrophic bogs, and buried soils. Plant macrofossils have been largely underutilized in other contexts, particularly lakes. Carefully and creatively designed studies using macrofossils and pollen together can greatly advance our understanding of vegetational and biogeographic history. Macrofossil analysis should be incorporated at early stages of paleoecological study design, site selection, and core location rather than as an ad hoc addition to studies centering on pollen and/or paleolimnology. This may require more sites (the best macrofossil sites may not be the most suitable for pollen records and vice versa) and multiple cores (to maximize macrofossil representation and temporal resolution simultaneously). Utilization of macrofossil-rich deposits, such as fluvial sediments, can lead to great advances. Such deposits record species poorly represented in lacustrine sediments and can yield large quantities of megascopic macrofossils capable of species identification. Pre-Quaternary paleobotanists focus on these kinds of sediments, with excellent results, and Quaternary paleoecologists would benefit from adopting similar approaches when possible. Plant macrofossil study in subtropical and tropical regions is vastly underdeveloped; few studies have assessed the

potential for tropical macrofossil analysis. Continued development of public-access macrofossil databases (e.g., www.ncdc.noaa.gov/paleo/plantmacros.html) is needed to support synoptic-scale studies, and macrofossil analysts must continue to be active contributors and users of these databases. Finally, systematic studies of macrofossil taphonomy are needed to support inferences and test assumptions.

Arctic Eurasia

Compared with Arctic North America, there are relatively few macrofossil records available in Arctic Eurasia. In Western Eurasia, repeated glaciations (Figure 1) abraded older Pleistocene organic material. The most important archives in North Europe and West Siberia are therefore post glacial peat and lake sediments. Plant macrofossil studies focus there on the chronology of recolonization of deglaciated areas during the Late Glacial and the Holocene (Alm and Birks, 1991; Birks, 1991, 2000; MacDonald et al., 2006).

Siberia, east of the Taymyr Peninsula, is situated outside the range of Pleistocene inland glaciations (Figure 1). As a result of the extreme shallowness of the wide northeast Siberian shelf seas, this region is affected by huge coastline shifts during Quaternary sea-level fluctuations. During Pleistocene sea-level lowstands, East Siberia together with Alaska and western Yukon formed a large land bridge and a common bioregion – Beringia (Figure 1). Instead of large ice sheets, there formed thick ice-bonded permafrost deposits, which perfectly preserve organic material over tens of thousands of years and are therefore an excellent archive of fossil organism remains (Figure 2). Not only plant remains but also carcasses of large herbivores are exceptionally well preserved in perennially frozen conditions. They sometimes include even the gastrointestinal content, which gives unique insights into the dietary spectrum of Pleistocene animals (Tomskaya, 2000; van Geel et al., 2008). Also, burrows of ancient rodents may reveal the former food base of herbivores (Gubin et al., 2001).

Several Quaternary key sequences in the Northeast Siberian coastal lowlands became known as recently as the second half of the last century (Giterman et al., 1982; Kaplina, 1980; Romanovskii, 1961); initially, however, macrofossils were sparsely studied. In recent years, systematic multidisciplinary studies have resulted in a considerable increase in available macrofossil records. The results have confirmed that plant macrofossils are key proxies for the reconstruction of

Quaternary terrestrial environments, compensating for the limitations of pollen analyses in the far North. In this article, results and climatic implications of Quaternary plant macrofossil studies in arctic Eurasia are discussed, with focus on Northeast Siberia.

The Arctic Today

The Arctic is regarded as the region north of the polar circle. In consequence of the Earth's axial precession, the high latitudes are characterized by extreme seasonal fluctuations of incoming solar radiation, culminating in the semiannual alternation of polar day and polar night. Due to the low altitude of the sun in the sky, the radiant flux density is very low. Nevertheless, the radiation balance is positive in summer and, owing to the polar day, the radiation supply during the growing season is among the highest in Eurasia. In a geobotanical sense, the Arctic is the region of tundra beyond northern treeline, which correlates approximately with the 10 °C mean July isotherm in West Eurasia or with the 12 °C July isotherm in the more continental East.

In today's Arctic tundra, a cool and short growing season is assumed to be the cause of treelessness and the main factor limiting arctic life. Both factors depend highly on the degree of maritime influence on climate. Proximity to the sea results in smaller seasonal temperature amplitudes, thus relatively mild winters, cool summers, and increased humidity. Due to the proximity of the Arctic Ocean and the North Eurasian shelf seas, the whole Eurasian Arctic tundra region is more or less under maritime climate influence today (Figure 3). Maritime influence involves increased cloudiness, which hampers the warming of the Earth's surface by direct solar radiation. Heightened precipitation brings thick snow cover in winter and saturated soils in summer. Because of the late snow melt, the growing season is very short and a high percentage of received solar energy is lost to snow albedo or is transformed in latent, not sensible, heat, because of waterlogged soils. In regions with

Figure 1 The northern hemisphere during the last cold stage. The figure illustrates the positions and maximum extents of northern inland ice sheets and the dimension of shelf exposure in North East Siberia (yellow signature) resulting in the formation of the subcontinent Beringia. Note the presence of ice-dammed lakes in West Siberia and the rerouting of rivers via the Turgay Pass into the Aral and Caspian Seas. Reproduced from Mangerud J, Jakobsson M, and Alexanderson H (2004) Ice-dammed lakes and rerouting of the drainage of northern Eurasia during the Last Glaciation. *Quaternary Science Reviews* 23 (11–13): 1313–1332. Bathymetric map adapted from the NGDC, NOAA Satellite and Information Service, available at <http://www.ngdc.noaa.gov/mgg/global/>.

a more continental climate, both insolation during summer and energy emission during winter can pass through the cloudless atmosphere much more easily. This results in higher seasonal temperature amplitude. Despite lower mean annual and winter temperatures than in the more maritime Europe and West Siberia, the polar treeline is shifted farther northward in East Siberia, owing to the relatively high summer mean temperature and lengthened growing season (Figure 3).

The composition of tree species that constitute the northern treeline changes longitudinally. The westernmost treeline constituent is the Scandinavian *Betula pubescens* ssp. *tortuosa*, replaced by *Picea obovata* eastward to the Ural Mountains, *Larix sibirica* in West Siberia, and *Larix dahurica* in Yakutia – the most continental part of the Arctic. In the Far East, the stone birch (*Betula ermanii*) is the northernmost tree species. The boreal coniferous forests in North Europe and West Siberia mainly composed of spruce and, in the south, fir are termed dark taiga. In Central and East Siberia, boreal forests are named light taiga owing to the appearance of the foliage of the constituting deciduous larch species. Other tree species that advance close to the northern treeline are *Pinus sylvestris* in Europe and *Chosenia arbutifolia* and *Populus suaveolens* in the Far East. Northern boreal coniferous forests fade to tundra gradually via the forest-tundra ecotone, where trees slowly diminish northwards. Trees advance farthest northward along river valleys, which are favored climatically due to energy transport by river water from the south and faster warming of the sandy floodplain soils (Walter, 1974). Furthermore, soils are better drained owing to the unfrozen ground (formation of taliks) in river valleys. Finally, the impact of winter storms on vegetation is alleviated in river valleys.

Figure 2 Quaternary permafrost exposures at the NE-Siberian coastal district Oyogos Yar. (a) Ice-bonded permafrost (Yedoma) exposed at the sea coast in up to 40 m high cliffs. (b) Warm-stage deposits of a former shallow lake trapped in an ice wedge cast. Fossil organism remains are well preserved in permafrost: *in situ* mammoth tusk (c), plant material accumulated in lacustrine deposits (d), including fruits of boreal aquatics (e) – *Potamogeton* sp. *in situ*. Photographs by F. Kienast.

The vegetation north of the treeline is relatively uniform. Many genera and even species in tundra have a circumpolar distribution. As refuge and center of dispersal, Beringia is floristically, however, more diverse than Arctic Europe and West Siberia – a result of the lack of inland glaciations and a more stable continental climate throughout the Quaternary. Due to the northward decrease of summer temperature, tundra is differentiated into two subzones by coverage and floral composition (Aleksandrova, 1980). The border between the arctic and subarctic tundra subzones is approximately determined by the 6 °C July isotherm. Subarctic tundra includes the forest-tundra ecotone and the southern tundra, which is characterized by the presence of boreal floral elements, such as *Duschetia fruticosa*, Ericaceae, *Empetrum nigrum*, *Comarum palustre*, *Rubus*, etc. Dwarf shrubs are the typical life form in subarctic tundra. Among them, dwarf birches (*Betula nana*, *Betula exilis*, *Betula glandulosa*) are most characteristic of this subzone. They are, in the arctic tundra, replaced by arctic willows such as *Salix polaris*, *Salix reticulata*, cold adapted cushion plants, arctic

Figure 3 Mean July air temperature (after Voeikov, 1981) and northern treeline in NE-Asia (green, after CAVM Team, 2003). Both July isotherms and treeline are correlated with the course of the coast line, which determines the maritime influence on climate. For example, on the maritime influenced Chukotka Peninsula in the Far East, the mean July temperature is about 8 °C, whereas at the same latitude (65° N) in continental Yakutia it is about 16 °C. The boreal treeline approximately follows the 12 °C mean July isotherm. The July temperature is highest in the most continental part of northern Asia – in Central Yakutia, where winter temperatures are among the lowest in the northern hemisphere.

sedges (*Carex stans*), and mosses. Boreal floral elements are largely absent in the subzone of arctic tundra.

As in every vegetation zone, tundra is composed of a mosaic of various plant communities which are controlled by a variety of local environmental factors. Due to the frozen ground, tundra soils are often saturated. Consequently, wetland vegetation, mainly composed of sedges, cotton grass, grasses, mosses, and dwarf shrubs, mostly on leached and acidic soils or on thick peat, dominates the landscape (CAVM Team, 2003). Small-scale vegetation differentiation is the result of uneven moisture or drainage, as a result of irregular snow cover thickness and active layer depths.

Permafrost affects soils and thus vegetation by stabilization and damming groundwater. Under humid climate, permafrost highly amplifies soil paludification. Today even in Arctic Northeast Siberia, where precipitation is less than 200 mm,

humid conditions prevail since temperature and evaporation are low. The landscape is characterized by widespread wetlands because of the damming effect and the melting of ice-rich permafrost deposits (Figure 4). Under arid climate conditions farther inland in contrast, permafrost is accompanied by high seasonal fluctuations of soil moisture due to high evaporation during summer. Here, permafrost supports salt accumulation in the soil by damming groundwater and supplying additional moisture and solutes (Yelovskaya et al., 1966; Figure 4).

Quaternary Key Sites in Arctic Eurasia

As already pointed out, permafrost deposits are among the most important paleoenvironmental archives in the Arctic. In

Figure 4 Permafrost impact on soils. Near-surface permafrost can amplify extreme soil conditions by damming and supplying melt water and solutes – wetness in humid situations (a) and salinification under arid conditions (b) and (c). Paludified arctic tundra at Oyogos Yar (a). Shore of a shrinking thermokarst lake in the extremely continental Central Yakutia with a seasonally fluctuating water level (b) and salt crust formation in the range that falls dry in summer (c). Photographs by F. Kienast (a) and C. Siegert (b) and (c).

Figure 5 Plant macrofossil key sites (black dots) and the distribution of ice-bonded permafrost (Yedoma, blue signature) in Arctic Eurasia. The occurrence of Yedoma is correlated with extremely low winter temperature and maximum continentality at the time of its formation during the last glacial, when the coast line was farther north (note the 100 m isobaths). Blue wedges indicate the presence of Yedoma restricted to river valleys. Site numbers correlate with Table 1. Yedoma distribution adapted from Romanovsky NN (1993) *Osnovy Kriogeneza Litostery*. Moscow: Izdatelstvo Moscow State University.

East Siberia, large areas are covered by ice-bonded permafrost (Yedoma, Ice Complex, Figures 2(a) and 5), which formed under very low winter temperatures during the last cold stage, when climate was extremely continental due to sea-level lowering and coast line regressions. Such ice-rich permafrost deposits probably formed likewise during older cold stages. Owing to their high ice content, ice-rich permafrost deposits are however thermally very susceptible and eroded repeatedly during warm stages. As a result, cold-stage deposits older than Late Quaternary are scarcely available. From the time prior to the Early Weichselian cold stage (MIS 4) therefore, only interglacial

macrofossil records are known. Moreover, owing to uneven permafrost degradation, the stratigraphical correlation of permafrost deposits in arctic regions is often complicated and records recognized without doubt as older than MIS 5 are rare. For the ecological interpretation of paleobotanical data, the stratigraphical correlation of fossiliferous deposits is crucial. Table 1 gives an overview of Quaternary plant macrofossil key sites in Siberia. Please note that many Russian records processed during the last century seem to be not fully published or publications are unavailable for the international audience (e.g., records discussed in Kaplina (1981) and Giterman et al. (1982)).

Quaternary Vegetation History

Macrofossil studies are generally part of multidisciplinary approaches. Through the combination of other paleoecological proxies such as sediment characteristics, pollen, and remains of herbivorous insects and mammals, we know much about the character of landscape and vegetation during the Quaternary by now, even though indicative upland plant taxa are often rare in the record. Especially, records older than middle Pleistocene are biased in composition through the dominance of aquatic plants, as they were deposited during warm stages exclusively in aquatic environments.

Pliocene

The Pliocene key sites available in the Eurasian Arctic prove that boreal coniferous forests existed in northern Siberia until the inception of northern hemisphere inland glaciations at the

beginning of the Quaternary about 2.6 Ma ago. These taiga forests were more diverse floristically, composed of now extinct conifers, several larch species, spruce, and pine (Giterman et al., 1982; Kaplina, 1981; Nikitin, 2006). Many extinct or extralimital thermophilous plants including *Epipremnum cras-sum*, *Nuphar pumila*, *Brasenia* sp., and *Potamogeton omoloicus* indicate conditions distinctly warmer than the present. However ice wedge casts in the upper Pliocene Kutuyakh beds indicate that permafrost already existed (Kaplina, 1981). Also the dominance of larch species might indicate harsh winter conditions. Due to their situation inland of the greatest land-mass on Earth and completely cut off from moist and mild Pacific air masses by the upfolding of the Himalaya Mountains, the northeast Siberian taiga forests had already evolved from the late Miocene onwards connected with progressive global cooling and increasing continentality. The transformation of northern vegetation in response to colder and more continental conditions during the Quaternary occurred in

Northeast Siberia on a greater scale and earlier than elsewhere in the northern hemisphere (Frenzel, 1968). The subsequent, increasingly abrupt Quaternary climate fluctuations were alleviated in Northeast Siberia because of its already established climatic continentality that more or less endured during the Quaternary, during both cold and warm phases.

Early and Middle Pleistocene

Many Pliocene conifers did not survive the onset of the Quaternary in NE Siberia, resulting in the domination of *Larix dahurica* in the Yakutian coastal lowlands (Giterman et al., 1982; Kaplina, 1981; Nikitin, 2006), probably connected with the very low winter temperature. Early and middle Pleistocene paleobotanical records in the arctic lowlands of Siberia reflect the existence of an open larch taiga – a dry grassland mosaic with lakes that were populated with thermophilous aquatics (e.g., *Damasonium stellatum*, *Sagittaria natans*) and salt-tolerant riparian plants, which are typical of shores at shrinking lakes under arid conditions (*Ranunculus sceleratus*, *Atriplex* sp., *Chenopodium* sp.). In contrast to modern tundra or northern taiga, dry habitats were widespread during early and middle Pleistocene interglacials as is indicated by the presence of steppe plants (*Linum perenne*, *Allium* sp.; Kaplina et al., 1983). The early Pleistocene cold stages were probably not as harsh as the later Saalian and Weichselian glaciations. This is indicated by the diversity of thermophilous, extralimital plants and the absence of extremely cold resistant mammals during the first cold stages (Sher, 1997). Tundra steppe was the dominant vegetation during cold stages, closely connected with the Mammoth faunal complex. As apparent from pollen records, the vegetation was much more uniform across broad regions than it is today, due to smaller latitudinal and longitudinal climate gradients in Eurasia. This seems to have been true not only during glacials but even during interglacials. The kind of today's latitudinal zonation of vegetation apparently did not exist (Sher, 1997).

The Last Interglacial – MIS 5

The last interglacial vegetation in Arctic Eurasia is represented here by two recent macrofossil records from the Krest Yuryakh Suite at about 73° N. The sequence consists of lake sediments filling large ice wedge casts and outcrops along the coasts of the Dmitry Laptev Strait (Figure 2) at both sides, the coastal mainland district Oyogos Yar (Kienast et al., 2011) and the Bol'shoi Lyakhovsky Island (Kienast et al., 2008). The coastal exposures are the first sites in NE Siberia, where last interglacial thermokarst deposits were described (Romanovskii, 1961). Both Eemian macrofossil records are only about 80 km apart, but they already reflect a floristic latitudinal gradient. Whereas trees were absent at today's coast of Bol'shoi Lyakhovsky Island, macrofossils of larch and tree alder have proven the existence of trees at the mainland coast Oyogos Yar at 72.68° N during the last interglacial (Figure 6). Accordingly, the northern treeline was at that time situated between both sites and had shifted by almost 300 km north of its current position. Thus, there existed trees at a place that is today (during the subsequent interglacial) too cold even for the survival of dwarf birches. Larch remains at other last interglacial exposures in

the tundra lowlands of Yakutia, for example, in Achchaggy deposits at the Allaikha River west of the Indigirka River (Kaplina et al., 1980) and the Bolshoy Khomus Yuryakh site east of the Indigirka River, (Lozhkin and Anderson, 1995) suggest that the treeline shift close to the arctic sea coast was a widespread phenomenon. Quantitative reconstructions resulted in a mean temperature of the warmest month of about 12 °C at the Bol'shoi Lyakhovsky Island and exceeding 13 °C at Oyogos Yar, thus about 9 °C warmer than today. Apart from the evidence of trees, warming is indicated by the diverse occurrence of Ericaceae such as *Arctostaphylos uva-ursi*, *Rhododendron* sp., *Chamaedaphne calyculata*, and *Andromeda polifolia* as well as aquatic plants, all of them far beyond their modern limit, for example, *Potamogeton perfoliatus*, *Potamogeton vaginatus*, and *Myriophyllum spicatum* (Figure 6). The last interglacial in western Beringia was not only warmer but also drier than today as is indicated by the remains of steppe plants such as *Allium*, *Artemisia*, *Androsace septentrionalis*, and *Potentilla stipularis*; xerophilous arctic plants such as *Kobresia*, *Ranunculus affinis*, and *Potentilla nivea*; and salt-tolerant pioneer plants of lake littorals, for example, *Chenopodium*, *Tripleurospermum maritimum*, and *Puccinellia* (Figure 7). Corresponding

to cold-stage records but in contrast to the current warm stage, alkali grass (*Puccinellia*) was among the most abundant plant taxa in the Eemian macrofossil spectra. All the indicators of dryness and fluctuating groundwater and lake levels indicate low net precipitation and, in conjunction with high summer temperature, a climate distinctly more continental than today.

The Last Cold Stage

The last cold stage (Weichselian) was the time of maximum continentality, when NE-Siberian coastlines retreated as far as 800 km northward (Figure 5) due to a global sea-level fall of up to 120 m. As the Laptev and East Siberian Seas are not deeper than 30 m over most of their extent, the shelves remained exposed and continentality persisted during the Mid-Weichselian interstadial (MIS 3) also, when there was a slight rise in the global sea level. Correlated with extreme low winter temperature, ice-bonded permafrost formed in the arctic lowlands and in large river valleys (Figure 5). Yedoma

deposits are frequently exposed and accessible along coastal and river bluffs in the arctic lowlands (Figure 2(a)). From there, a number of sites have been studied for plant macrofossils in recent years: Cape Sabler (Site 13, Figure 5; Kienast et al., 2001), Mamontovy Klyk (Site 12, Figure 5; Schirrmeister et al., 2009), Nagym (Site 9, Figure 5; Schirrmeister et al., 2010), Kurungnakh Sise (Site 11, Figure 5; Wetterich et al., 2008), Mamontovy Khayata (Site 10, Figure 5; Kienast et al., 2005), and Bol'shoi Lyakhovsky Island (Site 8; Andreev et al., 2009). The macrofossil records are more or less similar in species composition and partly resemble also assemblages from last interglacial Krest Yuryakh deposits at the Dmitri Laptev Strait. In contrast to the latter, thermophilous forest or aquatic plant species are however mostly lacking. Some boreal aquatics such as *Callitriche hermaphroditica*, *Potamogeton vaginatus*, and *Batrachium* sp. were still present during the Mid-Weichselian interstadial. The most characteristic feature of arctic vegetation during the last cold stage is, however, the coexistence of steppe

Figure 7 Macrofossils of aridity-indicator plants. 1–10 steppe plants; 1 *Linum perenne*, seed; 2 *Phlox sibirica*, capsule valve; 3 *Artemisia* sp., achene; 4 *Allium* sp., seed; 5 *Koeleria cristata*, floret; 6 *Potentilla stipularis*, nutlet; 7 *Androsace septentrionalis*, seed; 8 *Alyssum obovatum*, seed; 9 *Rumex acetosella*, fruit; 10 *Silene repens*, seed; 11–15 xerophilous arctic plants; 11 *Kobresia myosuroides*, nutlet; 12 *Thalictrum alpinum*, fruit; 13 *Ranunculus affinis*, nutlet; 14 *Potentilla nivea*, nutlet; 15 *Dryas octopetala* s.l., leaf fragment; 16–22 indicators of fluctuating lake levels and salinification; 16 *Carex duriuscula*, nutlet; 17 *Tripleurospermum maritimum*, achene; 18 *Stellaria crassifolia*, seed; 19 *Rorippa palustris*, seed; 20 *Puccinellia* cf. *tenuiflora*, caryopsis; 21 *Rumex maritimus*, fruit; 22 *Chenopodium* sp., seed.

Figure 8 (a) Cold-arid 'Goltsy' region in the alpine belt of the Chersky Mountains (Northeast Siberia). The precipitation is too low to support a perennial snow cover or even a glacier. Note the vegetation differentiation dependent on exposure and soil moisture. (b) Steppe and alpine plants occur there side by side (here: *Festuca kolyomensis* and *Dryas punctata*). Figure 9 Littoral ruderals at the shore of a shrinking thermokarst lake used as a cattle watering place, in Central Yakutia, with *Rumex maritimus*, *Stellaria crassifolia*, *Puccinellia tenuiflora*, *Senecio congestus*, *Peucedanum salinum*, *Chenopodium rubrum*, among others. A salt crust has formed at the surface of the hardly disturbed soil. Photograph by F. Kienast.

plants such as *Linum perenne*, *Artemisia frigida*, *Allium schoenoprasum*, *Alyssum obovatum*, *Potentilla stipularis*, *Silene repens*, *Androsace septentrionalis*, *Phlox sibirica*, and *Koeleria cristata* with xerophilous arctic plants such as *Kobresia myosuroides*, *Dryas*, *Potentilla nivea*, *Thalictrum alpinum*, and *Ranunculus affinis* (Figure 7). This plant species combination is diagnostic for the Pleistocene tundra-steppe, mammoth steppe or steppe tundra, which is intrinsically tied to the grazing mammoth faunal complex. Tundra-steppe has no biome-sized modern analog, but there are many places with tundra-steppe relict vegetation, especially in mountainous regions of Yakutia, where continental climate encounters cool temperature (Figure 8; Yurtsev, 1982, 2001). Tundra-steppe vegetation was mosaic-like and comprised potentially productive meadows with *Puccinellia*, *Hordeum brevisubulatum*, *Elytrigia*, *Festuca*, and *Poa*, as is indicated by macrofossils in yedoma deposits (Figures 7 and 10). These grasses are typical of saline floodplains and indicate seasonally fluctuating groundwater and salinification due to high evaporation. Remains of plants occurring at the littoral of shrinking lakes especially under saline influence, for example, *Rumex maritimus*, *Chenopodium*, *Tephrosia palustris*, and *Stellaria crassifolia* also indicate fluctuating lake water level due to high evaporation under arid conditions (Figure 9). Other steady components of the cold-stage plant macrofossil records are arctic pioneer plants such as *Papaver* Sect. *Scapiflora*, *Draba*, *Cerastium*, *Minuartia rubella*, and *Selaginella*, indicating locally open, disturbed ground. Northern wetland vegetation represented by macrofossils of *Carex*

Figure 10 *Puccinellia tenuiflora* (loose panicles) and *Hordeum brevisubulatum* (large spikes) growing in a floodplain meadow around a thermokarst lake in Central Yakutia. The productive meadow is intensively used as pasture. Photograph by F. Kienast.

Sect. *Phacocystis*, *Eriophorum scheuchzeri*, and *Eriophorum brachyantherum* played rather a minor role in the vegetation cover.

Late Glacial and Holocene

This period marks a fundamental alteration of northern ecosystems connected with the disappearance of tundra steppe and the extinction of many large herbivores such as mammoth, woolly rhinoceros, steppe bison, and Irish elk in high latitudes. The inception of the early Holocene began with a rapid temperature rise about 11.6 ka ago. The decay of ice caps was however delayed by about 5 ka and the global sea level reached modern values no earlier than 6 ka ago (CAPE-Last Interglacial Project Members, 2006). In consequence of delayed sea-level rise, the wide Laptev and Northeast Siberian Shelves remained long exposed (Bauch et al., 2001) and today's coastal sites were farther inland and remained influenced by persisting continentality during the early Holocene. Consistently, xerophilous plants continued to exist in the Arctic beyond the Weichselian/Holocene transition, for example, *Potentilla*, *Kobresia myosuroides*, and *Androsace septentrionalis* (Kienast et al., 2005; Wetterich et al., 2008). The increase of wetland plants such as *Carex* Sect. *Phacocystis* and *Eriophorum* spp. in the record, however, reflects paludification connected with the onset of thermokarst processes. The start of the accumulation of peat deposits on Chukotka and at the European ice sheet margins documents increasing moistening already during the Late Glacial between 14 and 12 ka (MacDonald et al., 2006). Wetlands expanded thereafter rapidly from 11.5 to 8 ka succeeding the retreating ice sheets in Fennoscandia and supported by increasing precipitation and thermokarst processes in Siberia (MacDonald et al., 2006). In the second half of the Holocene, wetland plants obtained absolute domination in arctic vegetation. Remains of xerophilous plants are no longer detectable in late Holocene macrofossil records. Northern latitude tundra steppe is intrinsically linked to the mammoth faunal complex. A macrofossil record with numerous remains of xerophilous plant taxa such as *Kobresia*, *Potentilla nivea*, and *Selaginella rupestris*, radiocarbon dated to about 10 ka BP, reveals that during the early Holocene, tundra-steppe vegetation dominated on Wrangel Island (Vazhenina, 1996),

the place where mammoth survived the longest (Stuart et al., 2002).

The early Holocene summer temperature shift was the consequence of high summer insolation combined with initially persisting continentality. As a result, boreal shrubs and trees returned into the far North. The expansion of woody taxa and the chronology of reforestation in the whole Eurasian North during the last glacial and the Holocene was recently reconstructed using a newly created macrofossil database (Binney et al., 2009). Accordingly, trees and shrubs expanded spreading from refugia that existed through the last cold stage in northern latitudes, as is suggested by scattered macrofossils, for example, larch remains in a mammoth stomach at 74°N on the Taymyr Peninsula dated about 21 ka BP (Mol et al., 2006). Adaptable ambiguous woody taxa such as birches and shrub alder, which persisted in northern refugia, rapidly occupied potential forest habitats and reached tree sizes (Edwards et al., 2005). Linked to continentality, deciduous trees such as larch and birch expanded rapidly, extending far beyond their present limit (Binney et al., 2009; Kremenetski et al., 1998; MacDonald et al., 2000). Reforestation peaked between 10 and 8 ka ago, when all treeline species including the evergreen spruce and pine reached their maximum Holocene distribution, probably connected with decreasing seasonality and increasing moisture (Binney et al., 2009). Further increasing maritime influence resulted in paludification. Cooler summers led to a new treeline retreat beginning after about 7 ka cal BP in eastern Siberia and culminating between 4 and 3 ka cal BP in Europe and West Siberia. From then on the modern low-diverse wetland tundra was established as the prevailing vegetation at high latitudes.

Reconstruction of Quaternary Vegetation

The basic character of Arctic vegetation during Pleistocene cold stages differed substantially from modern tundra. Within the Pleistocene tundra-steppe vegetation, there coexisted a wide range of plant communities, reflecting a variety of habitat conditions. Due to a greater spatial environmental gradient, the set of plant communities, constituent plant taxa, and habitat conditions was much more diverse than modern tundra and depended on the availability of warmth and moisture. During the Pleistocene these two factors fluctuated considerably, both seasonally and spatially. Modern tundra in contrast is rather shaped by consistently cool and wet conditions. The most important plant communities that occurred in the Arctic during the Quaternary are briefly described below.

Aquatic Vegetation

Most aquatic plants found in high-latitude Pleistocene cold-stage assemblages do not occur so far north today. The occurrence of boreal or even temperate aquatics in the Arctic indicates warm summers during cold stages, a result of increased continentality. Aquatic plant diversity peaked during interglacials as a result of high summer temperature and lengthened growing season. The occurrence of species tolerant of brackish water (e.g., sheathed pondweed (*Potamogeton vaginatus*)) can be traced

back to fluctuating salt contents in freshwater due to high evaporation under arid conditions inland. These species have very restricted modern ranges, but were widespread in the Pleistocene. According to Mai (1985), warmth-indicating southern aquatic plants had already expanded rapidly during the initial stages of interglacials or during treeless interstadials in Central Europe, even exceeding their spread in earlier warm stages. These phenomena can be ascribed to the rapid dispersal of aquatics by birds after the reestablishment of favorable conditions. Apparently, summer temperatures rose abruptly at the onset of warm stages. Freshwater aquatics are pioneers and can occupy suitable habitats very quickly, whereas most tree species disperse slowly and can only become established following sufficient soil formation.

Littoral Pioneers and Riparian Ruderals

Littoral pioneer plants, which occur on wet, bare, erosive soils along the shores of shallow lakes and ponds with seasonally fluctuating water levels, indicate unstable moisture conditions. Fluctuating moisture is characteristic of continental climate as occurred in the Arctic during the Pleistocene. This vegetation shows that lakes and pools, filled with water after snow melt, decreased in size or even dried up in the course of summer owing to high aridity (Figure 4(b) and 4(c)). Similar to aquatics, some littoral plants are facultative halophytes. Their tolerance of high-salt content in soils further strengthens the indication of high evaporation given by their pioneer character. Some representatives, such as saltmarsh grass (*Puccinellia* sp.), golden dock (*Rumex maritimus*), *Chenopodium* sp., and fleshy starwort (*Stellaria crassifolia*), found in Arctic East Siberian cold-stage deposits (Figure 7; Kienast et al., 2005) occur today primarily on the coast, and otherwise are only found in continental inland areas of Asia. Littoral ruderals cannot endure competition and disappear after the establishment of stable wet conditions fostering vegetational succession. In contrast, frequent disturbances by animals, for example, at watering places, promote this type of vegetation (Figure 9).

Meadows

Intense seasonal fluctuations of moisture and salt content in soil are also shown by the presence of saline meadows, which in Northeast Siberia were composed of saltmarsh grass (*Puccinellia* sp.) and wild barley (*Hordeum brevisubulatum*) as well as needle-leaf sedge (*Carex duriuscula*; Kienast et al., 2005). The constituent grasses are characteristic of floodplains around lakes outside the range of seasonal inundation under arid conditions (Figure 10). This vegetation type is productive due to its proximity to seasonally fluctuating groundwater. Also, in the Norwegian periglacial, meadows with saltmarsh grass (*Puccinellia*) existed during the Weichselian cold stage (Alm and Birks, 1991).

Steppe Vegetation

Fossil remains of grazing, steppe-characteristic mammals such as bison, horse, and saiga antelope together with extinct grazers such as mammoth and woolly rhinoceros in high-latitude cold-stage deposits in North America (Guthrie, 1990) and

Figure 11 Pingo on Kurungnakh Sise Island, Lena River Delta with xerophilous vegetation including *Potentilla stipularis*, *Ranunculus affinis*, *Dryas punctata*, *Delphinium middendorffii*, *Trisetum sibiricum*, *Artemisia* spp., *Draba* spp., and *Salix glauca* among others. Photograph by F. Kienast.

Eurasia (Sher et al., 2005) have suggested that grasslands must have been an important component of cold-stage environments in the Eurasian high latitudes during the Pleistocene. This presumption was supported by disjunctive arctic and subarctic occurrences of steppe vegetation in northern Siberia, which are considered to be relicts of a formerly closed and more northerly extended distribution area of those species (Yurtsev, 1982; Figure 8). Finally, the discovery of steppe plant macrofossils such as *Linum perenne*, *Artemisia frigida*, *Allium schoenoprasum*, *Alyssum obovatum*, *Potentilla stipularis*, *Silene repens*, *Androsace septentrionalis*, *Phlox sibirica*, and *Koeleria cristata* in arctic permafrost deposits dated to the last cold stage provided the ultimate proof that steppe plants typical of arid, continental climate were an important component of arctic cold-stage vegetation (Kienast et al., 2005; Zazula et al., 2006). The spectrum of steppe plant macrofossils in Arctic Siberia is illustrated in Figure 7.

Xerophilous Arctic Upland and Pioneer Vegetation

Macrofossils of plants that occur mainly in dry calcareous mountain tundra today likewise reflect dry conditions and climatic continentality during the Pleistocene. Such plants as *Kobresia myosuroides*, *Dryas octopetala*, *Potentilla nivea*, *Thalictrum alpinum*, and *Ranunculus affinis* (Figure 7) indicate little or no snow cover and occur today at exposed sites that are frequently disturbed by deflation in winter. Since restricted on dry, exposed places, such plants play a minor role in modern arctic lowland tundra and occur there only at isolated well-drained microhabitats such as pingos (Figure 11; Walker et al., 2001). Arctic pioneer plants, for example, *Draba* sp., *Minuartia rubella*, *Papaver* Sect. *Scapiflora*, and *Cerastium beeringianum* are also characteristic components of arctic vegetation during cold stages. They indicate locally open, disturbed ground and are able to withstand adverse environmental conditions. The northernmost vascular plants occurring today in Arctic deserts are characteristic species of arctic pioneer vegetation.

Shrub Tundra and Forest Tundra

As we have seen, woodlands with larch (*Larix*), birch (*Betula*), and alder (*Alnus*) extended during warm stages considerably northward far beyond their present limit. Forest tundra shifted up to the modern coast line in eastern Siberia. Some taxa actually forming shrubs today reached tree sizes during early stages of the Holocene and possibly also during older warm stages. The expansion of boreal trees and shrubs is correlated with a warm and lengthened growing season and the presence of well-drained soil. Shrubs, especially willow shrubs, are important and diverse constituents of Arctic vegetation during both cold and warm stages. Willow species composition of cold-stage floras, and their ecological significance, differs from those of warm stages. We are unable, however, to give environmental implications since most Arctic willows are impossible to identify by macrofossils except for leaves. Contrary to this, shrubs of black crowberry (*Empetrum nigrum*), dwarf birches, and Ericaceae such as berries (*Vaccinium* sp.), wild rosemary (*Ledum palustre*), and bearberry (*Arctostaphylos uva-ursi*) in Siberia give clear implications of a locally thick, protective snow cover and acidic soils, both characteristic of interglacials.

Snow-Bed Vegetation

Plant communities that are typical of snow beds occur at sites with thick snow cover and late snow melt on soils permanently soaked and cooled by melting water. Due to the long snow cover, the growing season is considerably shortened at such sites. Among vascular plants, *Ranunculus nivalis*, *Ranunculus pygmaeus*, *Saxifraga nivalis*, and *Saxifraga foliolosa* were found as macrofossils primarily in late Holocene records correlated with increased maritime influence, for example, low summer temperature and thick snow cover.

Wetland Vegetation

Plant communities that require constant moisture played a minor role during cold stages but became abundant during warm stages, not only because of increasing humidity but also due to thermal erosion of ice-rich permafrost, which resulted in extensive wetland formation. But as recently as during the late Holocene, wetland vegetation obtained absolute domination in high latitudes. Sedges (*Carex bigelowii*, *Carex stans*, *Carex arctisibirica*) and cotton grass (*Eriophorum scheuchzeri*) are characteristic plants of permanently wet mineral soils with circumneutral substrates. Dwarf birches, yellow marsh saxifrage (*Saxifraga hirculus*) and hares-tail cotton grass (*Eriophorum vaginatum*) occur at rather acidic mires after peat formation.

Discussion

The Quaternary is characterized by enormous changes of plant distribution rather than by evolutionary processes (Lang, 1994). According to the rule of relative habitat constancy (Walter, 1954), both individual plant species and plant communities compensate for climate shifts by relocation so that

their habitat conditions remain relatively constant. According to pollen and macrofossil records, all warm stages since the middle Pleistocene have been alike in tree composition (Frenzel, 1968). Coniferous forests decreased in diversity but remained conservative in their basic species composition during the Quaternary. Only their distribution has changed in response to climate oscillations, which resulted, during cold stages, in the expansion of steppe vegetation. The response of vegetation to global temperature fluctuations depends highly on changes in humidity. This is exemplified by the arctic vegetation history in the Quaternary.

Tundra is an interglacial vegetation type. As tundra became the prevailing vegetation in northern latitudes during the Holocene, the Pleistocene large herbivores became extinct. During the Pleistocene, wetland tundra was more constricted, also in warm stages. During thermal optima, forests expanded far north toward the coastline. Tundra existed primarily within the context of forest tundra. This is suggested by Eemian macrofossil records from the East Siberian Arctic, which have indicated that forest tundra with an admixture of steppe and meadow communities, combined with warmth-requiring aquatics, prevailed on the Laptev Shelf during the last warm stage (Kienast et al., 2008, 2010). The last interglacial paleovegetation indicates a greater seasonal temperature gradient, with summers distinctly warmer than today, and more variable moisture conditions. All the climatic implications point to more continental climate conditions persisting beyond the Saalian cold stage and giving rise to the assumption that the study site was inland during the Eemian interglacial. Consequently, the marine transgression during the last interglacial proceeded less than during the Holocene. It seems that the Holocene coast line advance exceeded all previous ones in Northeast Siberia. This might be caused by a subsidence of the shelf due to neotectonical spreading of the Laptev shelf and of parts of the East Siberian shelf. The large-scale transgression that took place in the course of the Holocene involved increasing maritime influence onto the climate of the whole region. Beringia of all Arctic regions was the major refuge for Arctic plants and animals. The increased maritime influence resulted in the transformation of vegetation toward modern tundra and in the loss of the mammoth faunal complex, which survived earlier warm stages in Beringia. It seems that proximity to the sea exerts more influence on regional climate in high latitudes than do global temperature trends. Summer temperature and growing-season length are crucial for life in the Arctic. Both depend on the degree of continentality.

This article is reproduced from the previous edition, volume 3, pp. 2434–2450, © 2007, Elsevier B.V.

This article presents a summary of our current knowledge of the vascular plant macrofossil record for northern North America from the onset of late Cenozoic glaciations (ca. 2.5 Mya) through the Holocene (all ages in calibrated or calendar years ago (ya)). The geographic range for this article extends from Alaska to eastern Canada, from the high Arctic to approximately 60° N ([Figure 1](#)). Where possible, we have used common names for the plants. [Table 1](#) lists the common names, scientific names, and ecological affinities of the taxa mentioned in this article. Citations and site details are included in [Table 2](#).

For the purposes of this article, we define plant macrofossils as vegetative and reproductive parts of vascular plants that may be seen with the naked eye. Vegetative parts include leaves or twigs, whereas reproductive parts include fruits, seeds, and flowers. Macrofossils contrast with megafossils, which typically refer to larger remains such as logs. Plant macrofossils may be recovered within, but are not restricted to, lacustrine cores, peat, colluvium, and alluvium. In rare circumstances, plant macrofossils are found as *in situ* buried vegetation where whole or partial plants are preserved in their former growth position.

Northern Climate and Landscapes

The broadest patterns of northern climate, now and in the past, are a function of latitude, proximity to oceans, and the influence of continental-scale topography ([Figure 2](#)). Coastal regions have maritime-type climates with relatively high precipitation totals and a lack of summer/winter temperature extremes. Interior regions have continental-type climates with lower precipitation totals and greater summer/winter extremes. In the High Arctic, precipitation is very low with cold winters and cold summers. In all regions, most precipitation occurs in the late summer to early winter, with a maximum on the southeastern Alaska coast (>2000 mm per year) and a minimum in the High Arctic (<50 mm per year).

The modern vegetation of northern North America is a mixture of forest and muskeg south of treeline and a variety of tundra types to the north (Flora of North America, 1993+; [CAVM, 2003](#)). In the forested region (boreal forest or taiga), coniferous or mixed forests dominate. In the western regions, white and black spruce are the dominant conifers, whereas in eastern regions jack pine and larch become dominant. In some areas, especially those affected by frequent forest fires, deciduous trees, such as resin birch, cottonwood, and aspen, become important forest components. The boreal forest also has a significant shrub component of willow, alder, birch, and various ericaceous shrubs.

Much of the forested region is underlain by discontinuous permafrost, which is often found on north-facing slopes or in valley bottoms. In these areas, the vegetation is a scattered scrubby black spruce or larch woodland interspersed with grasses and tussock-forming sedges. Mosses and acidophilic forbs and shrubs are also common. The soils are cold and poorly drained, often with standing water in the summer. The permafrost is easily disturbed in this region, resulting in pond formation (thermokarst) and catastrophic ground surface collapse.

Regionally, the northern limit of trees ([Figure 3](#)) is controlled by climate, but on a local scale, factors such as aspect and drainage exert a strong influence. Spruce and pine are the dominant treeline species across the continent, although stands of extralimital cottonwood are present in Alaska. Tree-line in central Canada is a gradational boundary, with a wide swath of lichen woodland and forest–tundra separating the closed forest from the tundra ([Elliott-Fisk, 2000](#)).

The tundra to the north is variable, ranging from a shrub-dominated vegetation to graminoid tundra and barrens. The key climatic variables controlling tundra vegetation are summer temperature and winter snow cover, but local factors, such as topography and substrate (because they affect soil temperature, snow depth, soil nutrient status, and drainage), also strongly influence the tundra vegetation ([CAVM, 2003](#)). Permafrost is continuous throughout the tundra zone, which affects the vegetation through a combination of cold soil temperatures, impeded drainage, and thermokarst. The shrub tundra is a mix of birch, alder, willow, and ericaceous shrubs with graminoids (sedge and grasses) and mosses. Graminoid tundra is dominated by herbs and forbs, whereas barrens are dominated by herbs, lichens, and mosses. Large areas of the tundra zone are very poorly drained and are dominated by wet sedge (often tussock forming) and grass meadows (sometimes with low shrubs).

Summary of Macrofossil Sites

Plant macrofossil analysis, conducted alone or in conjunction with other paleoecological methods, has greatly added to our understanding of Arctic vegetation history. Our discussion is limited to well-documented macrofossil sites for key time intervals in the Quaternary. Due to space limitations, we have not attempted to provide an exhaustive list of all sites that contain plant macrofossils. An important feature of all northern macrofossil sites is their excellent preservation, even for very old sites. This is due, especially in the High Arctic, to the presence of permafrost.

Figure 1 Localities mentioned in the text. Sites are marked by circles; site numbers correlate with [Table 2](#).

Table 1 Taxa mentioned in the text^a

<i>Taxon</i>	<i>Common name</i>	<i>Plant growth form</i>	<i>Typical site and biome</i>
Pteridophyta	Ferns	Herb	Boreal forest and tundra
Pinaceae			
<i>Picea</i> sp.	Spruce	Tree	Boreal forest
<i>Larix</i> sp.	Larch, tamarack	Tree	Muskeg, wet places, boreal forest
<i>Larix laricina</i> (Du Roi) K. Koch	Larch, tamarack	Tree	Muskeg, wet places, boreal forest
<i>Picea glauca</i> (Moench) Voss s.l.	White spruce	Tree	Well-drained to bogs, boreal forest
<i>Picea mariana</i> (Mill.) B.S.P.	Black spruce	Tree	Muskeg, poorly drained, boreal forest
<i>Pinus</i> (<i>Strobus</i>) subsect. <i>Cembrae</i>	Old World five-needled pine	Tree	Extinct in North America; east Asian origin
<i>Pinus</i> subsect. <i>Eustropei</i>	Old World two-needled pine	Tree	Extinct in North America; east Asian origin
<i>Pinus matthewsii</i> sp. Nov.		Tree	Extinct in North America; cone morphology similar to <i>P. contorta</i>
McKown, Stockey, and Schweger			
<i>Abies</i> sp.	Fir	Tree	Mountain slopes, acidic bedrock; forest
Typhaceae			
<i>Typha latifolia</i> L.	Cattail	Herb	Shallow water marshes; forest
Potamogetonaceae			
<i>Potamogeton vaginatus</i> Turcz.	Giant pondweed	Herb	Lakes, slow-moving rivers to 3 m depth; forest and tundra
<i>Zannichellia palustris</i> L.	Horned pondweed	Herb	Shallow (often brackish) water on edge of ponds; forest
Alismataceae			
<i>Alisma</i> sp.	Water-plantain	Herb	Emergent aquatic; southern boreal forest
<i>Sagittaria latifolia</i>	Common arrowhead, wapato, duck potato	Herb	Southern boreal forest
Poaceae			
<i>Deschampsia</i> sp.	Hair grass	Herb	Wet meadows, lakeshores, gravel bars; tundra and forest
<i>Elymus</i> sp.	Rye grass	Herb	Grassy slopes, well-drained, riverbanks; tundra and forest
<i>Glyceria</i> sp.	Manna grass	Herb	Shallow water, lakeshores, riparian, wet meadows; probably forest
<i>Hierochloë hirta</i> ssp. <i>arctica</i> G. Weim.	Sweet grass	Herb	Sandy stream banks, meadows, lakeshores; low Arctic & Alpine tundra
(= <i>H. odorata</i>)			
<i>Poa</i> sp.	Blue grass	Herb	Open slopes, stream banks; boreal forest and tundra
Cyperaceae			
<i>Carex</i> spp.	Sedge	Herb	Forest to tundra to grassland
<i>Kobresia myosuroides</i> (Vill.) Fiori & Paol.		Herb	Dry, calcareous sites; tundra
Araceae			
<i>Aracites globosa</i> (C. & E. Reid) Benn.		Herb	Extinct, wetland?
<i>Epipremnum crassum</i> C. & E. Reid		Herb	Extinct, wetland?

(Continued)

Table 1 (Continued)

<i>Taxon</i>	<i>Common name</i>	<i>Plant growth form</i>	<i>Typical site and biome</i>
Liliaceae			
<i>Allium</i> sp.	Wild onion	Herb	Grassy slopes, riverbanks, shorelines; forest and tundra
Salicaceae			
<i>Populus balsamifera</i> L.	Balsam poplar, cottonwood	Tree	Floodplains, alluvial flats, boreal forest
<i>Populus tremuloides</i> Michx.	Aspen	Tree	Open woods and along creeks, pioneer on burns; boreal forest
<i>Salix</i> sp.	Willow	Tree or shrub	Boreal forest or shrub tundra
<i>Salix arctica</i> Pall.	Arctic willow	Prostrate dwarf shrub	Sedge meadows to dry tundra and heath
Myricaceae			
<i>Myrica arctogale</i> Benn	Extinct sweet gale	Shrub	Extinct, bogs?
<i>Myrica gale</i> L.	Sweet gale	Low shrub	Mesic sites, boreal forest
Betulaceae			
<i>Alnus</i> sp.	Alder	Low or tall shrub	Stream banks, slopes, lakeshores; boreal forest and shrub tundra
<i>Betula glandulosa</i> Michx.	Shrub birch	Low shrub	Muskeg; forest and shrub tundra
<i>Betula nana</i> L.	Dwarf birch	Dwarf shrub	Muskeg; shrub tundra
<i>Betula neoalaskana</i> Sarg.	Alaska birch	Tree	Acid and peaty sites; boreal forest
<i>Betula papyrifera</i> Marsh.	Resin birch, paper birch	Tree	Open woodland; boreal forest
Polygonaceae			
<i>Polygonum</i> sp.	Knotweed	Herb	Pioneer, mesic sites, turfy sites, terrestrial and aquatic; forest and tundra
<i>Polygonum viviparum</i> L.	Alpine bistort	Herb	Turfy, rocky barrens, moist grassy herb mats; forest and tundra
Chenopodiaceae			
<i>Chenopodium</i> sp.		Herb	Disturbed areas, sandy, dry, often saline soils; forest and tundra
<i>Chenopodium simplex</i> (Torr.) Raf. (= <i>C. gigantospermum</i> Aellen)	Maple leaf goosefoot	Herb	Disturbed areas, hardwood slopes, wooded tallus slopes; forest
<i>Corispermum hyssopifolium</i> L.	Bugseed	Herb	Sandy sites, gravel bars on rivers; forest
Caryophyllaceae			
<i>Cerastium</i> sp.	Mouse-ear chickweed	Herb	Disturbed, grassy slopes, gravelly, meadows; forest and tundra
<i>Minuartia</i> spp.	Sandwort	Herb	Mesic or well-drained stony, gravelly, dry slopes; forest and tundra
<i>Silene involucreta</i> (Cham. & Schlecht.) Bocquet (= <i>Melandrium affine</i> J. Vahl)	Campion	Herb	Stony, gravelly, sandy, rocky sites; forest and tundra
Nymphaeaceae			
<i>Nymphaea</i>	Water lily	Herb	Emergent aquatic; boreal forest
Ranunculaceae			
<i>Ranunculus</i> spp.	Buttercup	Herb	Aquatic and terrestrial herbs; forest and tundra
<i>Ranunculus hyperboreas</i> type	Arctic buttercup	Herb	Shallow fresh or brackish ponds, mud flats, pond borders; forest and tundra
<i>Ranunculus aquatilis</i> L. (= <i>Ranunculus trichophyllus</i> Chaix)	White water buttercup	Herb	Submerged aquatic, sometimes calcareous ponds; forest and tundra
<i>Ranunculus lapponicus</i> L.	Lapland buttercup	Herb	Damp moss, willow thickets, bogs; mainly tundra
Papaveraceae			
<i>Papaver</i> sp.	Arctic poppy	Herb	Turfy sites, herb mats, gravelly, calcareous outcrops; tundra
Brassicaceae			
<i>Draba</i> sp.		Herb	Open slopes, calciphilous, mainly tundra
<i>Erysimum</i> cf. <i>cheiranthoides</i> L.	Wormseed mustard	Herb	Moist turf sites, creek banks, lake shores; forest and tundra
<i>Lepidium densiflorum</i> Schrad.	Common pepper-grass	Herb	Dry, open disturbed sites; forest and tundra
Rosaceae			
<i>Chamaerhodos erecta</i> L.	Little rose	Herb	Dry sandy gravelly slopes; forest
<i>Dryas</i> sp.	Mountain avens	Prostrate dwarf shrub	Disturbed, well-drained, dry, gravelly sites, calciphilous; forest and tundra

(Continued)

Table 1 (Continued)

<i>Taxon</i>	<i>Common name</i>	<i>Plant growth form</i>	<i>Typical site and biome</i>
<i>Potentilla</i> sp.	Cinquefoil	Herb or shrub	Often in well-drained disturbed sites, but also moist, turfy sites; forest and tundra
<i>Rubus spectabilis</i>	Salmonberry	Low shrub	Moist woods; coastal boreal forest
<i>Rubus idaeus</i> L.	Raspberry	Dwarf shrub	Thickets, edge of woods, riverbanks; forest
Linaceae			
<i>Linum lewisii</i> Pursh(= <i>Linum perenne</i> L.)	Flax	Herb	Meadows, gravelly banks, sandy areas; mainly forest
Empetraceae			
<i>Empetrum nigrum</i> L.	Crowberry	Dwarf shrub	Heath, swamps, bogs; forest and tundra
Hippuridaceae			
<i>Hippuris vulgaris</i> L.	Mare's tail	Herb	Emergent aquatic, shallow ponds, slow-moving streams, lakes; forest and tundra
Apiaceae			
<i>Bupleurum americanum</i> Coult. & Rose (= <i>B. triradiatum</i> Adams)	Thoroughwort	Herb	Meadows, moist sand, talus slopes, gravel banks; forest and tundra
<i>Sium suave</i> Walt.	Water parsnip	Herb	Emergent aquatic, muddy shores, stream and lake margins; mainly forest
Ericaceae			
<i>Andromeda polifolia</i> L.	Bog rosemary	Low shrub	Muskeg, moist meadows, wet tundra and boreal forest
<i>Arctostaphylos uva-ursi</i> (L.) Spreng. s.l.	Bearberry, kinnikinnick	Dwarf shrub	Exposed rocks, riverbanks, sandy sites, open woods; mainly forest
<i>Cassiope tetragona</i> (L.) D. Don		Dwarf shrub	Dry, rocky sites; tundra
<i>Chamaedaphne calyculata</i> (L.) Moench	Leatherleaf, cassandra	Low or dwarf shrub	Bogs, muskegs, lake margins; forest and tundra
<i>Ledum decumbens</i> (Ait.) Lodd.		Dwarf shrub	Heaths, dry, rocky sites; forest and tundra
<i>Ledum groenlandicum</i> Oeder	Labrador tea	Low shrub	Peat soils, bogs, muskeg; forest and tundra
<i>Vaccinium vitis-idaea</i> L.	Low bush cranberry, lingon berry	Dwarf shrub	Acid soils, muskeg; forest and tundra
Primulaceae			
<i>Androsace septentrionalis</i> L.	Pygmy flower	Herb	Dry rocky, sandy sites, disturbed sites, calcophile tundra and grasslands
Menyanthaceae			
<i>Menyanthes trifoliata</i> L.	Buckbean	Herb	Emergent aquatic, bogs, lake and stream margins; forest and tundra
Polemoniaceae			
<i>Phlox hoodii</i> Richards.	Moss phlox	Herb	Open slopes, dry tundra and grasslands
Lamiaceae			
<i>Lycopus</i> sp.	Tuberous water-horehound	Herb	Wet sand, lakeshores and along streams; forest
<i>Stachys</i> sp.	Hedge-nettle	Herb	Fields, clearings, hot springs, moist woods; forest
Caprifoliaceae			
<i>Sambucus</i> sp.		Shrub	Extinct species; modern sp. in moist woods and sub-Alpine meadows
Asteraceae			
<i>Artemisia frigida</i> Willd.	Prairie sagewort	Low or dwarf shrub	Open sandy slopes, disturbed sites; dry grasslands, rarely tundra
<i>Artemisia</i> sp.	Wormwood	Herb or shrub	Dry and mesic sites; forest and tundra
<i>Bidens frondosa</i> L.	Burr	Herb	Disturbed areas; shorelines; forest
<i>Taraxacum ceratophorum</i> (Ledeb.) DC. s.l.	Dandelion	Herb	Meadows and moist areas; forest and tundra

^aNomenclature follows Cody (1996). Common names, growth form, and typical site/biome are from personal observations, floras (Hultén, 1968; Cody, 1996), or, in the case of extinct taxa, from the cited reference (see Table 2). Shrub classifiers (tall, >2 m; low, 40 cm to 2 m; and dwarf, <40 cm) are from CAVM (2003).

Late Pliocene (3.6–1.8 Mya)

Although not Quaternary, the late Pliocene is an important time interval in Arctic North America because Quaternary-style continental glaciation began at this time and the modern flora

became established. Plant macrofossils from several sites across Arctic and sub-Arctic North America provide evidence for a floristically rich boreal forest that persisted until the onset of glaciation and Northern Hemisphere cooling approximately 2.5 Mya.

Table 2 Key sites mentioned in the text^a

Site No.	Age	Site name	Location	Unit and/or section	Key taxa	Inferred past vegetation	Modern vegetation	Source
1	Late Pliocene	Lost Chicken Mine	Central Alaska	LC-II: Unit L7	<i>Picea</i> , <i>Larix</i> , extinct <i>Pinus</i> (5-needle), <i>Aricites globosa</i> , <i>Sambucus</i>	Forest	Boreal forest	Matthews et al. (2003) <i>Quaternary Research</i> 60: 9–18
2	Late Pliocene	Ch'jee's Bluff	Northern Yukon Territory	Units 1 and 2	<i>Abies</i> , <i>Larix</i> , <i>Picea</i> , extinct <i>Pinus</i> (5-needle), <i>Pinus matthewsii</i> , <i>Aricites globosa</i> , <i>Menyanthes</i> , <i>Sambucus</i>	Forest	Boreal forest	Matthews and Ovenden (1990) <i>Arctic</i> 43: 364–392
3	Late Pliocene	Ballast Brook	Banks Island	Upper unit	Extralimital <i>Larix</i> , <i>Picea</i> , <i>Alnus</i> , <i>Betula</i> (tree type); extinct <i>Pinus</i> (2- and 5-needle), <i>Epipremnum crassum</i> , <i>Aricites globosa</i>	Forest	Barren or prostrate shrub tundra	Matthews and Ovenden (1990) <i>Arctic</i> 43: 364–392
4	Late Pliocene	Beaufort Formation	Meighen Island		Extralimital <i>Larix</i> , <i>Thuja occidentalis</i> , <i>Alnus</i> , <i>Betula</i> (tree type); extinct <i>Picea</i> , <i>Pinus</i> (2- and 5-needle), <i>Epipremnum crassum</i>	Forest	Barren or prostrate shrub tundra	Matthews and Ovenden (1990) <i>Arctic</i> 43: 364–392
5	Late Pliocene/early Pleistocene	Fish Creek	Northern Alaska		Extralimital <i>Larix</i> , <i>Alnus</i>	Boreal forest	Shrub tundra	Matthews and Ovenden (1990) <i>Arctic</i> 43: 364–392
6	Early Pleistocene	Cape Deceit	Seward Peninsula	Cape Deceit Formation	Extralimital <i>Larix laricina</i>	Northern boreal forest	Wetland tundra	Matthews and Ovenden (1990) <i>Arctic</i> 43: 364–392
7	Mid-Pleistocene	Duckhawk Bluffs	Banks Island	Morgan Bluff Formation	Extralimital <i>Picea</i> , <i>Larix</i> , <i>Betula</i> shrubs, <i>Menyanthes trifoliata</i>	Boreal forest	Graminoid prostrate dwarf shrub tundra	Matthews et al. (1986) <i>Géographie Physique et Quaternaire</i> 40: 279–298
8	Pleistocene	Makinson Inlet	Ellesmere Island		Extralimital <i>Menyanthes trifoliata</i> , <i>Andromeda polifolia</i>	Erect shrub tundra	Barren or prostrate shrub tundra	Blake and Matthews (1979) <i>Geological Survey Paper 79-1a, Current Research Part A</i>
9	Late Pliocene to mid-Pleistocene	Isortoq/ Flitaway	Baffin Island		Extralimital <i>Betula nana/glandulosum</i> , <i>Ledum groenlandicum</i> , <i>Vaccinium vitis-idaea</i>	Erect shrub tundra	Cryptogam barren	Morgan et al. (1993) <i>Canadian Journal of Earth Science</i> 30: 954–974

^aModern tundra classification is based on CAVM (2003).

Figure 2 Modern climate of northern North America. (a) Mean July temperature. (b) Mean January temperature. (c) Mean annual precipitation. The western Cordillera and highlands of southern Alaska help establish prevailing wind patterns from northwest to southeast, resulting in the temperature pattern exhibited here. The Cordillera also heavily influences the precipitation regime, largely preventing Pacific Ocean moisture from reaching interior lowlands. Maps are based on data obtained from the Climate Research Unit, University of East Anglia, and drawn using National Center for Atmospheric Research command language.

Key sites (Lost Chicken Mine in east central Alaska, Ch'jee's Bluff and Bluefish in the northern Yukon, Ballast Brook Upper Unit of Banks Island, NWT, the Beaufort Formation on Meighen Island, several localities on Ellesmere Island; **Figure 1**, sites 1–4; **Table 2**) document a boreal forest dominated by five-needle and two-needle pines, spruce, fir, and larch, all with northern boundaries much beyond their present positions. These assemblages typically also include several now extinct taxa (*Myrica arctogale* and *Aracites globosa*) or those currently restricted much further to the south (elderberry (*Sambucus*) and *Epipremnum crassum* (Aracaceae), suggesting much higher mean January temperatures (possibly up to 10–15 °C warmer) and greater precipitation than at present. Climatic transition by 2 Mya saw the loss of many Pliocene tree and shrub taxa, with spruce or larch (Fish Creek, **Figure 1**, site 5; **Table 2**) replacing pine as the dominant conifer in the boreal forest of Quaternary interglaciations.

Early to Middle Pleistocene (ca. 1.8–0.125 Mya)

This period marks the onset of the Quaternary, the hallmark of which is the climatic shifts between glaciations and interglaciations. Interglacial periods were similar to our own climate, at times warmer than today. Glacial periods were cold and dry, with continental-scale ice sheets isolating Alaska and north-west Canada from the rest of North America. One major effect of the enormous ice sheets is the drawdown of the world's oceans, exposing the Bering Land Bridge (BLB) between Alaska and Russia. The effects of the presence or absence of the BLB cannot be overemphasized. An exposed BLB allowed migration of terrestrial plants and animals between Russia and North America but blocked migrations and water flow between the Pacific and Arctic Oceans. In addition, because of greater distance from the ocean, this subcontinental-scale landmass increased continentality and aridity in regions bordering the modern Bering Sea.

Due to biases in preservation (macrofossils are more likely to survive in moist peaty situations typical of interglaciations), the macrofossil sites discussed in this section all date to interglacial periods, when climate was at least as warm as today. The Cape Deceit Formation on the Seward Peninsula (**Figure 1**, site 6) yielded abundant plant macrofossils, which presumably dates between the early and middle Pleistocene. Plant macrofossils include larch needles (**Table 2**), and microfossils include spruce pollen. The site today is west of treeline, indicating climate was slightly warmer than modern during the early to middle Pleistocene.

Several sites from the High Arctic of Canada, although not well dated, probably date to interglaciations of the early to middle Pleistocene. All these sites (**Table 2**) contain extralimital taxa, with strong evidence that treeline was significantly farther north than today. The Morgan Bluffs Formation on Banks Island (**Figure 1**, site 7) contains spruce and larch macrofossils in addition to shrub birch (which barely grows on Banks Island today). On Baffin Island, the Isortoq and Flitaway sites (**Figure 1**, site 9) contain extralimital low Arctic and tree-line shrubs (but no trees). On Ellesmere Island, peat deposits near Makinson Inlet (**Figure 1**, site 8) contain an ericaceous shrub and an emergent aquatic that today do not grow on the island.

Figure 3 Treeline across Alaska and Canada. The Alaskan section is based on the vegetation map provided in Viereck and Little (1972). The Canadian section is based on the satellite-based Canada Vegetation Cover map in the *National Atlas of Canada*, fifth edition (Energy, Mines, and Resources Canada, 1993).

Last Interglaciation (ca. 125–75 ka)

Long records from marine and ice cores indicate the last interglaciation (Marine Isotope Stage 5 (MIS 5)) was a period of shifting climate from warmer than modern to modern or slightly cooler than modern climate (Petit et al., 1999). The warmest part of the interglaciation was its onset (MIS 5e), when continental glaciers had largely disappeared, the Greenland icecap was significantly smaller than today (Koerner, 1989), and sea level was slightly higher than modern (Esat et al., 1999). In the north, MIS 5 is documented in lake cores, relict shorelines, and buried peat deposits (LIGA, 1991; CAPE Last Interglacial project members, 2006). Although it is often assumed that the sites indicating the warmest temperatures probably dated to MIS 5e, the possibility that some may date to one of the warm intervals after MIS 5e (i.e., MIS 5c or 5a) cannot be excluded.

In Alaska, macrofossil remains, especially spruce, indicate forest expansion beyond current limits to the Chukchi Sea and northwards to the Arctic Ocean. The sites include the Baldwin Peninsula (Figure 1, site 11), the Pelukian shorelines east of Barrow (Figure 1, site 12) (Hamilton and Brigham-Grette, 1991), and probably Cape Deceit (Figure 1, site 10) (Giterman et al., 1982). In northwest Alaska, fossil needles indicate spruce also migrated approximately 80 km beyond its current limit on the Noatak River (Figure 1, site 13; Table 2). Although treeline expansion in the north and west clearly indicates warmer than modern summer temperatures, the expansion on the Noatak

River is less clear and local factors such as permafrost distribution or disturbance may have been important.

In interior Alaska, at Eva Creek (Figure 1, site 15), the Palisades (Figure 1, site 14), and work in progress at Birch Creek indicate that the vegetation was not dramatically different from that of today. Minor differences include more abundant ferns (suggesting relatively warm, moist conditions) at some sites during MIS 5e and an extralimital aquatic (*Sagittaria latifolia*) that today grows only as far north as central British Columbia.

In the northern Yukon Territory, plant macrofossil analyses at Ch'ijee's Bluff and Hungry Creek (Figure 1, sites 16 and 17, respectively; Table 2) also indicate the presence of boreal forest similar to today's vegetation but with taxa close to or beyond their modern northern limits. Ch'ijee's Bluff, approximately 30 km south of the modern forest limit, supports a boreal forest in well-drained settings and black spruce bog in poorly drained areas. Macrofossils include abundant spruce needles, as well as several extralimital herbs and shrubs; these indicate not only the presence of a closed boreal forest but also that the forest was similar to forests growing in the southern Yukon today. Farther south, MIS 5-aged alluvium at Hungry Creek also contains herbaceous taxa near or slightly beyond their modern limits.

In the Canadian High Arctic, samples from the Collinson Formation on Banks Island (Figure 1, site 18) indicate northern migration of shrub tundra, but treeline was still south of the island. Sites from Bathurst Island (Figure 1, site 19) are

poorly dated but may date to MIS 5. These sites contain a few extralimital or rare taxa that are more common in tundra to the south.

MIS 3 (60–25 ka)

MIS 3 was a long period of climatic amelioration and reduced glacial ice volume over North America; however, the BLB remained a conspicuous part of Arctic paleogeography, at least during cool phases. Pollen assemblages and other proxy data suggest complex environmental fluctuations, with some intervals dominated by glacial herb–tundra, whereas others indicate spruce-dominated woodland or mixtures of tundra and forest (Anderson and Lozhkin, 2001).

MIS 3 sites in central Alaska include the loess/colluvial sediments of the Isabella Basin and loess and peat within the Fox Permafrost tunnel (Figure 1, sites 20 and 21, respectively; Table 2); however, chronological uncertainties make the interpretation of their paleoecological data troublesome. Although spruce needles were recovered from Isabella Basin, these may represent interglacial (MIS 5) rather than interstadial deposits (Hamilton and Brigham-Grette, 1991). Plant macrofossils from the Fox permafrost tunnel include graminoids, shrubs, aquatic herbs, and upland tundra forbs, which together with pollen and insect data suggest a mesic to dry tundra mosaic with open spruce stands in lower parts of sheltered valleys. Taken together, plant macrofossils indicate that interstadial conditions between 35 and 30 ka were less arid and less cold than during the early (MIS 4) and late Wisconsinan (MIS 2) intervals, enabling some local spruce to persist within tundra–forest vegetation.

Sites from the Stewart River, central Yukon, indicate the MIS 3 vegetation was variable. The older locality (Mayo section, ca. 38 ka) contains a rooted willow stump with spruce needles and significant amounts of spruce pollen, suggesting the climate may have been similar to modern. However, by approximately 29.6 ka, macrofossils from alluvium at the Mayo Indian Village (MIV; Figure 1, site 22) (just downstream of the Mayo section) include shrubs and diverse tundra herbs typical of well-drained sites, suggesting a tundra environment that was probably no colder than present low Arctic tundra, although it was probably drier (Figure 1 and Table 2). Although a single spruce needle at MIV was considered to be reworked, pollen data suggest there may have been some small groves of trees in sheltered localities, indicating that altitudinal treeline was depressed by at least 850 m from present.

Periglacial dune deposits of the Kittigazuit Formation (Figure 1, site 23), dated to 37–33 ka on the Tuktoyaktuk coast, contain a macrofossil assemblage including diverse dry land steppe–tundra herbs, plants of moist meadows, emergent aquatics, shrubs, and some spruce needles (Figure 1 and Table 2). This assemblage suggests aridity with saline ponds and possibly warmer than present summers. It is unclear whether the spruce needles were found *in situ*. If they are not reworked, this would indicate that scattered trees may have also been present; today the northern limit of spruce is approximately 50 km south of the site.

The available macrofossil evidence from MIS 3 suggests that, with the exception of Kittigazuit Formation, the northern

limit of the boreal forest was somewhat south of today's limit and tundra formed the most widespread vegetation type. The Kittigazuit Formation and MIV both contain *Corispermum hys-sopifolium* and other herbs more typical of dry sites, indicating at least local aridity.

MIS 2 (25–16 ka)

Due to the buildup of glacial ice in the Northern Hemisphere, worldwide sea levels were lowered by approximately 120 m 21 ka, during the Last Glacial Maximum (LGM) (Fairbanks, 1989). In North America, this resulted in the exposure of the BLB between Alaska and Russia, forming Beringia, which extends from eastern Siberia to the Mackenzie River in Canada (Hopkins et al., 1982). Climate reconstructions based on a variety of climate proxy data indicate the Northern Hemisphere cooled at least 5 °C (Ruddiman, 2002). In Beringia, extensive active dune fields, loess deposition, and, in interior Alaska, a near absence of lakes also indicate a very dry climate (Hopkins et al., 1982).

Much previous discussion on full-glacial environments in Beringia has centered on the so-called mammoth steppe or the productivity paradox (Hopkins et al., 1982). This debate has attempted to resolve how the diverse Pleistocene mammoth fauna could survive harsh full-glacial conditions at high latitudes when much paleoecological data suggest the presence of a low-productivity tundra vegetation. Most of what we know about Beringian vegetation during MIS 2 is based on fossil pollen data, indicating the vegetation was a tree- and probably shrub-less herb tundra. However, the presence of grazing large mammals suggests widespread grassland or steppe habitats to provide adequate fodder. Since the dominant pollen taxa (grass (Poaceae), sedge (Cyperaceae), and sage (*Artemisia*)) cannot be identified with greater taxonomic resolution, they have been interpreted as indicative of either steppe or tundra. Thus, the floristic composition, structure, physiognomy, productivity, and spatial distribution of Beringian vegetation cannot be recognized by pollen alone. Recent macrofossil studies from diverse settings have shed light on this discussion and suggest that Beringian vegetation is more complex than the tundra versus steppe dichotomy as postulated previously.

Macrofossils preserved in cores from the Bering Shelf (Figure 1, site 24; Table 2) document this now drowned landscape. Shallow freshwater bog plants, sedges, and pondweed dominate MIS 2- and Late Glacial-aged (ca. 21–16 ka) samples. The vegetation was clearly mesic at the coring localities, with few arid-adapted upland taxa recovered. No arboreal or shrub macrofossils were recovered, although common birch pollen suggests shrubs may have been growing nearby. Taken together, these plant macrofossils represent low-lying mesic to wet birch–graminoid tundra with interspersed ponds.

Probably the best LGM aged plant macrofossil site in Alaska is the buried Kitluk soil found under a 21-ka tephra on the Seward Peninsula (Figure 1, site 25; Table 2). This *in situ* vegetation provides a unique view of a plant community that inhabited an upland, calcareous loess soil near central Beringia during the height of the last glaciation. The plant macrofossil assemblage is dominated by graminoids, specifically the xerophilous sedge *Kobresia myosuroides*. The forb flora on the

buried surface is diverse and includes many taxa typical of dry to mesic calcareous substrates. Prostrate willows (including *Salix arctica*) are present but very rare. Taken as a whole, macrofossils on the LGM upland vegetation on the Seward Peninsula indicate a treeless vegetation mosaic dominated by closed, dry herb tundra–grassland but with some low-growing willows in moister localities.

MIS 2-aged sites from the boreal forested regions of Yukon Territory provide information on the vegetation that occupied the continental interior of eastern-most Beringia. Key sites are ice-rich loess deposits in the Klondike valleys of west-central Yukon (Figure 1, site 27) that contain valley bottom peat and fossil Arctic ground squirrel (*Spermophilus parryi*) middens (dated ca. 27 ka) and low-energy alluvial deposits at the Bluefish exposure (ca. 21–18 ka) in the northern Yukon (Figure 1, site 26; Figure 4; Table 2). Together, well-preserved remains of graminoids, diverse forbs, as well as leaves and/or flowers of

the prairie sage dominate these deposits. These floristically diverse assemblages suggest that plants that are currently common in dry to mesic Alpine tundra and azonal steppe communities formed local steppe–tundra ecotonal mosaics.

Holocene Macrofossil Records (ca. 11 ka to the Present)

The early Holocene (ca. 11–8 Ka) is marked primarily by warmer than modern summer temperatures but colder winters (COHMAP members, 1988). The vegetation reflects this climatic regime by the northward and westward advance of tree-line in Alaska and Canada (Table 2). Wood and leaves from cottonwood or aspen have been collected beyond treeline in western Alaska (ca. 50 km to the west) and on the Arctic coastal plain (ca. 100 km to the north) (Mann et al., 2002). In western Canada, the northward migration of treeline is recorded by spruce and larch needle and/or wood fragments on the

Figure 4 Selected macrofossils from MIS 2 in Yukon Territory (see [Zazula et al., 2006](#)). Scale bars in A–G are 0.1 mm. (a) *Chenopodium* sp. seed; (b) *Papaver* sp. seed; (c) *Potentilla* sp. achene; (d) *Cerastium* sp. seed; (e) *Draba* sp. seed; (f) *Taraxacum ceratophorum* achene; (g) *Phlox* cf. *hoodii* capsule fragment; (h) *Artemisia* flower, ca. 3 mm; (i) *Artemisia frigida* leaves; (j) *Kobresia myosuroides* achene; (k) *Festuca* sp. floret; (l) *Elymus trachycaulus* florets.

Tuktoyaktuk Peninsula (Figure 1, sites 29 and 30) and *Populus* wood from sites on the shores of the Arctic Ocean in the Yukon and Northwest Territories.

The Laurentide Ice Sheet persisted in eastern Canada until the mid-Holocene (Dyke et al., 2002). In northern Quebec, macrofossil records indicate that treeline has remained stable since deglaciation; however, larch needles preserved in peat do indicate a slight expansion beyond its current limit approximately 3.5–2.7 and 2.0–1.6 ka (Figure 1, site 37; Table 2) (Payette et al., 2002).

Peatland development was widespread during the Holocene (Ovenden, 1990), but the extent to which it reflects climate is still debated. Holocene-aged macrofossil records from throughout the north (Figure 1 and Table 2 sites 31, 32, 33 and 34) document site drainage and the development of a relatively rich fen, followed by a transition to a comparatively poor bog or heath vegetation. The time of fen development is dependent on when the site became ice-free. Deglaciation was earliest in the northwest (ca. 15 ka in the northern Yukon) and latest in the east (ca. 6 Ka at Hudson's Bay), so fen development was earliest in the Yukon and western NWT (ca. 12.5–10 Ka) and later in central Nunavut (ca. 8.0 Ka) and at Hudson's Bay (ca. 5.6 Ka).

The transition to bog or heath reflects changes in the local hydrology at the sites. The primary drivers of these changes is either permafrost expansion or autochthonous peat development that may be independent of permafrost. Permafrost expansion can lead to either drying and a heath vegetation (due to the development of high-centered polygons) or wetting and a bog vegetation (due to the development of low-centered polygons). Autochthonous peat development may also dry a site by raising the vegetation above the water table, resulting in a heath vegetation.

Holocene-aged peat deposits in the High Arctic may provide some information on regional climates (Figure 1 and Table 2, sites 35 and 36). Dates of peat development in areas that no longer support thick peat deposits may provide evidence for moister climate in the past (Garneau, 2000); however, local topography and hydrology may be more important factors (La Farge-England et al., 1991).

Discussion

Range Extensions

Much of the macrofossil data presented here document range extensions, especially treeline shifts. Plant macrofossils are a particularly robust proxy for documenting treeline because (1) species-level identification is possible and (2) compared to pollen, macrofossils travel comparatively short distances. At sites where larch is the dominant conifer, larch needles are more easily recognized than larch pollen, which is fragile and nondescript. Another example is *Populus*; *Populus* pollen does not travel far from its source and is easily degraded so that although Alaskan pollen records indeed indicate expansion of *Populus* during the early Holocene (Anderson et al., 2004), it is the macrofossil evidence that clearly shows a range extension.

Much of the modern treeline is defined by the northern limit of spruce and pine. Pollen from both of these taxa travel widely so that 10% spruce and, in places, 30% pine pollen

mark the northern limit of trees (Anderson et al., 1991). Macrofossils (wood, needles, and stomata) provide excellent evidence that the tree was actually growing at the site (Payette et al., 2002).

Knowing the location of treeline in the past is critical for reconstructing the climate and ecology of the region. The modern treeline is influenced by the thermal regime, usually characterized as mean July temperature or accumulated radiation (Elliott-Fisk, 2000). During the late Pliocene, pines grew on Meighen Island, implying at least an 8 °C increase in summer temperatures. Pleistocene interglacial peat deposits also indicate northward expansion of treeline, although not as extreme as during the late Pliocene.

MIS 5 is of particular importance because it is the most recent interglaciation that we can compare with our own. Range extensions of spruce trees near the Arctic Ocean, boreal forest herbs in the Yukon, and tundra shrubs in the High Arctic (if the Bathurst Island site dates to MIS 5) indicate warmer than modern temperatures. However, compared with MIS 5-aged sites elsewhere in the Arctic (LIGA, 1991; CAPE Last Interglacial project members, 2006), the amount of summer warming across northern North America was modest—probably on the order of 1° or 2 °C.

Vegetation Reconstructions

In addition to documenting the local presence of a taxon, because of their high taxonomic resolution, macrofossils provide more exact vegetation reconstruction than is possible with pollen analysis alone. This is especially important when analyzing the Beringian full-glacial vegetation of MIS 2.

The dominance of grass, sedge, and diverse tundra and steppe forbs at MIS 2-aged macrofossil sites in the Yukon suggests plants that are currently common on dry to mesic alpine tundra and azonal steppe communities formed local steppe–tundra ecotonal mosaics. The local composition and distribution of this vegetation was closely related to landscape position, aspect, available moisture, and disturbance (Figure 5). The presence of *Artemisia frigida* leaves is significant because this suggests at least some of the *Artemisia* pollen from MIS 2-aged sites derives from this dry-adapted taxon.

The detail afforded by plant macrofossils has helped establish a picture of substantial floristic diversity during the LGM, at both the local and the regional scale. Tundra herbs were more abundant in some areas, whereas steppe plants were common in others. Vegetation in Beringia during MIS 2 cannot be easily classified as either steppe or tundra because floristic analogs can be drawn with several vegetation types. These studies demonstrate how plant macrofossil-based vegetation reconstructions can resolve local-scale floristic composition that cannot be achieved by pollen analysis alone.

Conclusion

Plant macrofossil records provide important details on climate and vegetation. The exact placement of treeline during different times in the past and the detailed full-glacial vegetation reconstruction are two examples. However, because of biases in deposition and preservation, macrofossil records should also

Figure 5 Idealized vegetation–topography sequence for continental eastern Beringia during MIS 2, relating the effects of altitude, drainage, and substrate on vegetation composition. Adapted from Zazula GD, Schweger CE, Beaudoin AB, and McCourt GH (2006) Macrofossil and pollen evidence for full-glacial steppe within an ecological mosaic along the Bluefish River, eastern Beringia. *Quaternary International* 142–143: 2–16.

be interpreted conservatively and modern macrofossil taphonomy studies should be a priority. The absence of a particular macrofossil at a particular site does not mean the taxon is absent from the landscape, highlighting the importance of paired pollen and macrofossil analyses for well-rounded paleoecological reconstructions (Birks, 2001).

Introduction

The Greenland subcontinent is the largest island on Earth, covering an area of 2 166 086 km². The ice-free land between the central Greenland ice sheet (the Inland Ice) and the surrounding waters is up to 250 km broad, and covers 410 449 km². Numerous local ice caps and other types of glaciers are found, as well as large fjords (Figure 1).

Major parts of ice-free Greenland are mountainous, with Alpine topography or plateau landscapes dissected by valleys. Many parts of the landscape show strong influence from glacial erosion, with rounded mountains. But in other areas hardly any sign of glacial erosion is seen between the valleys or fjords.

The deep ice cores from the Inland Ice have aroused a large interest among Quaternary geologists and paleoclimatologists, because they provide a wealth of detailed information about the climatic development in the North Atlantic region during the last Ice Age and the Holocene. However, these investigations provide little information about the biotic reactions to the climatic changes.

The ice-free parts of Greenland only give glimpses of the pre-Holocene vegetation history. Due to the repeated glaciations many deposits have been removed by eroding glaciers and meltwater rivers. In spite of this, the pre-Holocene deposits may give a fairly detailed picture of plant life. Holocene deposits are much more widespread and detailed studies of changes of vegetation and flora history have been conducted.

A review on the vegetation history of West Greenland was provided by Fredskild (1985a) and a review of the Quaternary history of the ice-free parts of Greenland was published by Funder (1989). Analyses of the Holocene vegetation history were started by J. Iversen and were continued primarily by Fredskild (1967, 1973, 1978, 1983, 1985b, 1995, 2000), Funder (1978), Bennike (1999, 2000), and Bennike et al. (1999). Pre-Holocene floras have been reported by Bennike (1990), Bennike and Böcher (1992, 1994); and Björck et al. (2002). In addition to pollen analysis, plant macrofossil analyses have also been conducted. Studies of macroscopic plant remains have been especially important for reconstruction of pre-Holocene and early Holocene vegetation, mainly because pollen is poorly preserved and because plant macrofossils can often be identified to species, whereas pollen can usually only be identified to genus or family.

Present-Day Climate

Greenland spans 24° of latitude, corresponding to 2675 km, which means that marked climatic differences are seen from south to north. The mean summer temperature shows a fall from 11 °C in the south to 2–3 °C in the far north, and the mean winter temperature falls from –4 °C to –30 °C. The precipitation also decreases toward the north, from about

2500 mm yr^{–1} in the far south to below 200 mm yr^{–1} in parts of northern Greenland. In addition, a strong climatic gradient exists from an oceanic type of climate at the outer coast to a more continental climate near the margin of the Inland Ice.

In the central parts of North Greenland, the fjords are covered by land-fast sea-ice all year round, but farther south a period of open water occurs, and the harbors in the southwestern part of Greenland are navigable throughout the year. West Greenland is strongly influenced by the relatively warm, northward flowing West Greenland Current, whereas East and South Greenland are influenced by the cold southward flowing East Greenland Current.

Modern Flora and Vegetation

Considering the size of the ice-free land areas in Greenland, the present species diversity is relatively small. This is primarily due to the northern geographical location and the low temperatures, but it also reflects the rather isolated position of Greenland. The flora comprises ca. 480 species of seed plants, 35 species of pteridophytes (ferns and allied), ca. 600 species of bryophytes (mosses), and ca. 950 species of lichens. Thirty-two woody plant species are found.

Shrubs and heaths are widespread in the lowlands of Greenland, and furthest south, at 60° N, small areas with birch forest are found. In South Greenland, some farming takes place. Furthest to the north, at 83° N, areas of polar desert, without any woody plants, are found. Fell-fields with scattered plants are found on windy places where the snow is blown away during the winter. Herb slopes, snow beds and mires are also widespread.

Terminology and Dating

The terms early, mid-, and late Holocene are used informally, and Late Glacial is used for the time span between 14 and 11.7 ka BP, corresponding to Greenland interstadial 1 and Greenland stadial 1. The last Ice Age corresponds to marine isotope stages 2–5d, and the last interglacial stage to marine isotope stage 5e. Pre-Holocene deposits have mostly been dated by paleomagnetism, luminescence dating, amino acid analyses, and strontium isotope analyses. Younger deposits have been dated by radiocarbon dating, and dates have been calibrated to calendar years BP, which are used here.

Chronology of the Last Deglaciation

During recent decades a lot of data have been gathered that throw light on the chronology of the deglaciation of the ice-free land parts of Greenland. On this basis a chronology for the last recession of the Inland Ice was proposed by Bennike and Björck (2002). At the outer coast the oldest dates are between

Figure 1 Map of Greenland showing the location of place names mentioned in the text.

11.5 and 10 ka whereas areas near the margin of the Inland Ice were deglaciated between 8000 and 6000 ka. In the far south, the oldest sediments recovered date to 14.1 ka, and the interior of the fjords were deglaciated in the early Holocene.

Late Glacial and Holocene Climate Changes

As mentioned above, on-shore Late Glacial deposits have only been located in South Greenland. Analyses of one sequence indicate that the Younger Dryas was relatively mild in this region (Björck et al., 2002). The abrupt warming at the Younger Dryas to Holocene boundary was followed by a more gradual warming, which was interrupted by short cooling events in the early Holocene. The Holocene is characterized by a marked thermal maximum, during which many plants extended their northern geographical range limit northwards. The Holocene thermal maximum is broadly dated to between 8 and 6 ka, preceding cooling that culminated in the Little Ice Age.

At many sites in Greenland evidence is found that both the Inland Ice and local glaciers were smaller than at present during the mid-Holocene. The best-dated glacial history comes from Nioghalvfjærdsfjorden in northeastern Greenland. The fjord is, at present, covered by a 60 km long floating outlet glacier from the Inland Ice, but the fjord was ice free during a continuous period from 7.8 to 4.5 ka BP (Bennike and Weidick, 2001).

Signs of mid-Holocene declining temperatures are also seen in many pollen diagrams from Greenland. For example,

decreasing *Betula nana* (dwarf birch) pollen percentage values in East Greenland at around 5.6 ka BP and decreasing *Juniperus communis* (juniper) pollen percentage values in southwest Greenland around 4.5 ka BP reflect falling summer temperatures (Funder, 1978; Fredskild, 1983).

The Kap København Formation

Cooling during the Tertiary led to buildup of ice sheets in the polar regions, first in Antarctica, and later in the Arctic. Deposits in the circum-Arctic region show that Pliocene temperatures were relatively high. Rare plant macrofossils on Île de France in NE Greenland give a glimpse of the vegetation at around 3.4 Ma (Bennike et al., 2002). The material comprises remains of *Picea* cf. *mariana* (black spruce) and *Thuja* sp. (cedar). These taxa indicate that the land was covered by coniferous forest or forest-tundra, with a mean temperature for the warmest month of the year over 10 °C, corresponding to at least 6 °C more than at present. Occurrences of old wood at other sites in northern Greenland are also referred to the Pliocene. Such wood is particularly common in Washington land, where *Pinus* (pine) wood is common.

The Kap København Formation is a sequence of deltaic, fluvial and marine clay, silt, and sand deposits in eastern North Greenland. The formation contains a wealth of well-preserved remains of nonmarine plants and animals, with many different groups represented. The most diverse group is beetles, of which at least 210 species are present, a surprising number when compared with the modern-day beetle fauna of Greenland that comprises around 40 species (Böcher, 1995). Vascular plants from the Kap København Formation include a mixture of boreal and Arctic species (Bennike (1990); Figure 2). Taxa such as *Larix groenlandii* (Greenland larch), *Picea mariana*, *Thuja occidentalis* (northern white-cedar), *Taxus* sp. (yew), and *Betula* sect. *Albae*

Figure 2 Drawings of plant remains from the Kap København Formation. (a), (b): Leaves of *Dryas octopetala* (mountain avens). (a) Shows a leaf that comes from a plant that grew on a protected site; (b) shows a leaf with re-curved leaf margin, which comes from a plant that grew on a wind exposed site. (c), (d): Leaves of *Betula nana* (dwarf birch). (e) Fruit stone of *Cornus stolonifera* (red-osier dogwood). (f) Cone of *Larix groenlandii* (Greenland larch). Remains of these species occur in the Kap København Formation, the location of which is shown by a black dot in northern Greenland.

Figure 4 Scanning electron microscope photographs of plant remains from the last Interglacial. (a) Catkin scale of *Alnus* cf. *crispa* (green alder); (b) Leaf of *Dryas octopetala* (mountain avens); (c) Leaf of *Vaccinium uliginosum* (Arctic blueberry); (d) Endocarp of *Arctostaphylos alpina* (Alpine bearberry); (e) Leaf of *Phyllodoce coerulea* (mountain-heath). The scale bars correspond to 1 mm.

(tree birch) belong to the first group (Figure 3), whereas *Dryas octopetala* (mountain avens) and *Oxyria digyna* (mountain sorrel) belong to the second. All remains of wood come from small trees or shrubs, and the maximal trunk diameter is 18 cm. Growth rings are narrow to extremely narrow, which together with the composition of the flora, indicate that the mean temperature for the warmest month of the year was 10–11 °C. This corresponds to 7 °C higher than at present. *Thuja* and *Taxus* cannot tolerate very cold winters, and the mean temperature for the coldest month was probably not below –17 °C. It appears that the area was dominated by forest-tundra and an oceanic type of sub-Arctic climate.

The dating of the Kap København Formation is based on a number of different methods, of which the most important are biostratigraphy, paleomagnetic analyses and amino acid analyses. The biostratigraphically most important groups are foraminifers, marine ostracodes, marine mollusks, and mammals. The occurrence of the extinct rabbit *Hypolagus* sp. and the extant hare *Lepus* sp. have been particularly important. These genera co-occurred during the time period from ca. 2.3 to 2.0 Ma. A correlation with marine isotope stages 91–101, corresponding to 2.35–2.52 Ma, has been proposed (Funder et al., 2001).

The Last Interglacial

A rather large number of mid-Pleistocene marine interglacial occurrences have been located in Greenland, but these do not provide information about the vegetation. In contrast, layers from the last interglacial are found on many localities along

the south and west coast of Jameson Land in East Greenland. The deposits are mainly sand, silt, and clay, which were deposited in shallow water along the coast. At many sites, layers and lenses rich in organic detritus are found. This detritus consists of washed-together remains of plants that grew in the catchment area. The detritus also contains remains of insects and other invertebrates. These remains give a regional picture of the biotas.

The flora includes remains of many species of other woody plants (Figure 4). Most noteworthy are common remains of the tree birch *Betula pubescens* (downy birch), which probably formed copses or low forest on sheltered sites. At present, tree birch is confined to southernmost Greenland, whereas *Betula nana*, common today in Jameson Land, has not been found in the interglacial deposits. On moist localities, alder was growing, probably *Alnus crispa* (green alder), which grows in southwestern Greenland and North America at present. Another woody plant found in interglacial deposits that still grows in southernmost Greenland is *Cornus canadensis* (creeping dogwood) (Figure 5). Dwarf shrubs are represented by no less than 11 species, of which the majority are ericaceous. Fruits and leaves of *Empetrum nigrum* (crowberry) are especially common. Leaves of the snow-bed species *Salix herbacea* (herb-like willow) are also common.

The dwarf shrubs are characterized by Arctic species such as *Dryas octopetala*, *Cassiope tetragona* (white Arctic bell-heather), and *Arctostaphylos alpina* (Alpine bearberry). The fossil assemblages are also rich in remains of herbs and bryophytes. The bryophyte flora with more than 60 identified taxa also includes some southern extralimital species.

Figure 5 Map over the northern parts of the Earth, showing the present day geographical ranges of (a) *Betula pubescens* (downy birch); (b) *Alnus crispa* (green alder); and (c) *Cornus canadensis* (creeping dogwood). Remains of these species occur in layers from the last interglacial stage in Jameson Land (black dots).

One of the most warmth demanding plant species from the interglacial layers is *Betula pubescens*, which indicates a mean temperature for the warmest month of at least 10–11 °C, corresponding to 5 °C higher than at present. The deposits from Jameson Land have been dated by numerous luminescence dates, which place the deposits in the last interglacial.

Marine deposits from the last interglacial are also fairly widespread in the Thule area in northwest Greenland. Remains of nonmarine plants and animals have been located at a single coastal cliff section. Some of the taxa represent southern extralimital occurrences. These comprise the bryophytes *Pleurozium schreberi* and *Conardia compacta* and the vascular plants *Selaginella selaginoides* (lesser clubmoss), *Menyanthes trifoliata* (buckbean), *Betula* sect. *Nanae* (dwarf birch), and *Gentiana detonsa* (serrate gentian) (Bennike and Böcher, 1992; Hedenäs and Bennike, 2003). The mean temperature for the warmest month of the year was at least 4 °C higher than at present. The layers at Thule are also primarily dated by means of luminescence dating.

In northern Greenland, two sites with plant remains have yielded nonfinite radiocarbon dates. The flora indicates summer temperatures similar to those found in the region at present, which may imply that the deposits belong to an interglacial rather than to an interstadial.

The Last Ice Age

Hugin Sø Interstade

In Jameson Land, the Hugin Sø Interstade, which is correlated with marine isotope stage 5c, represents an ice-free period. The vegetation appears to have consisted of herbs and bryophytes only. Remains of *Saxifraga oppositifolia* (purple saxifrage) are common, and seeds of *Papaver* sect. *Scapiflora* (arctic poppy) also occur. These species are found all over Greenland at present, but they play an increasing role in the vegetation toward the north, and none of them have been found in deposits from the last interglacial. It has been proposed that the mean temperature for the warmest month of the year was 3–4 °C lower than at present (Bennike and Böcher, 1994).

The Last Glacial Maximum

In central Greenland, the temperature minimum during the last Ice Age is dated to about 22 ka BP, and the mean annual temperature was about 25 °C lower than at present. If these

results can be transferred to the marginal parts of Greenland, only the hardest plants could have survived the last Ice Age. The extent of the Inland Ice was far larger than at present during the Last Glacial Maximum and large parts of the extensive shelf areas around Greenland were also covered by the ice sheet.

The Late Glacial

Late Glacial sediments from two localities in southern Greenland have been analyzed for pollen and plant macrofossils (Björck et al., 2002). The concentration of pollen is extremely low, and a large part must be regarded as long-distance transported. Pollen of Poaceae (grasses), *Sagina* type (pearlwort), and *Saxifraga* (saxifrage) presumably come from the local vegetation, and the same applies to a few seeds of *Minuartia* sp. (sandwort), *Saxifraga* cf. *oppositifolia* and Poaceae (grasses). The unstable soils were characterized by a pioneer vegetation with mosses and scattered herbs.

Holocene Vegetation Development

The vegetation development after the last deglaciation in the different parts of Greenland has obviously been different, but nevertheless it can be divided into three main phases: a pioneer phase, a phase of optimum productivity, and a recessional phase. The development reflects direct and indirect climatic forcing, and problems in colonizing the country. The vegetation development has mainly been constructed from regional pollen diagrams from lake deposits. The most important pollen diagrams from South and West Greenland have been published by Fredskild (1973, 1983, 1985a, b). From East Greenland, pollen diagrams have been published by Funder (1978). In the northern parts of Greenland it has proved difficult to find lakes with continuous sequences, and the extremely low pollen production also leads to problems. From these parts of Greenland only a few well-dated pollen diagrams have been published. In West Greenland, some diagrams extend back to the earliest Holocene, whereas none of the diagrams from East and North Greenland covers the first one or two millennia of the Holocene. In addition to pollen analyses, macroscopic plant remains have also been analyzed at many sites, partly to investigate early Holocene floras (Bennike et al., 1999).

Figure 6 Summary diagram showing the known temporal range of different taxa in Greenland after the last deglaciation (Holocene and Late Glacial).

The pioneer phase is characterized by bryophytes, herbs and grasses, by species that can tolerate low summer temperatures and unstable soils (Fredskild, 1985a; Bennike, 1999; Bennike et al., 1999). In southern Greenland, pollen of *Oxyria digyna* can account for up to 75% of the pollen sum. In eastern Greenland, macrofossils of *Papaver radiculatum* (arctic poppy), *Oxyria digyna*, and *Melandrium apetalum* (nodding lychnis) are present in earliest Holocene deposits (Figure 6). The pioneer phase may have extended over several millennia in the peripheral parts of Greenland, which were deglaciated first. In the inland, the pioneer phase was of shorter duration, because most of Greenland's plant species had immigrated when these parts became ice free, so that a more diverse flora could rapidly colonize these areas.

The first woody plant that appears to have immigrated to Greenland is *Empetrum nigrum*, which was present from ca. 11 ka BP. It was soon followed by *Salix herbacea*, which is known from 10.8 ka BP, and *Vaccinium uliginosum* (Arctic blueberry), which is known from 10.5 ka BP. Other ericaceous dwarf shrub species were also early immigrants.

After a transitional stage a productivity optimum is seen. Although regional differences are evident, large parts of Greenland's lowlands became covered by dense dwarf shrub heaths. This development reflects soil stabilization as species immigrated and summer temperatures increased. In the far south, birch copses expanded, but in the north, fell-field vegetation prevailed. *Betula nana*, *Salix* spp. (willow), and a number of ericaceous plants such as *Empetrum nigrum*, *Vaccinium uliginosum*, and *Cassiope tetragona* came to dominate the heaths.

Gradually decreasing summer temperatures in the mid- and late Holocene led to decreasing pollen production and more open heaths. The northern range limit of some species, such as *Empetrum nigrum*, *Armeria scabra* (thrift), and *Potamogeton filiformis* (slender-leaved pondweed) moved south.

Figure 7 shows a summary diagram from southernmost Greenland as an example of a Greenland pollen succession

Figure 7 Summary pollen percentage diagram for the Holocene, based on several lakes in the Kap Farvel area in southern Greenland.

(Fredskild, 1973). The pioneer vegetation was dominated by grasses, *Saxifraga*, *Cerastium* (chickweed), and *Sagina*, followed by peaks of *Koenigia islandica* (common koenigia) and *Oxyria digyna*. Different dwarf shrubs, such as *Loiseleuria decumbens* (Alpine azalea), *Harimanella hypnoides* (moss heather), and *Empetrum* were early immigrants. *Angelica archangelica* (angelica) was also an early immigrant, whereas *Salix*, *Juniperus communis*, and *Betula* arrived later. The short-lived marked peak of grass pollen may be synchronous with the 8200 event (Fredskild, 1973). It has not been detected in other Greenland pollen diagrams, but the resolution of most diagrams is too low to allow short events to be detected. Declining *Juniperus* and *Betula* values mark declining summer temperatures in the late Holocene.

Another example of a Greenland Holocene pollen succession is provided by a simplified diagram from the inner part of the Godthåbsfjord in SW Greenland (Figure 8; Fredskild (1983)). The pioneer vegetation was rich in grasses, sedges, and *Oxyria digyna*. *Empetrum* is also here present at an early stage, whereas *Salix glauca* (northern willow) did not immigrate until about 8.7 ka BP. Around 7.4 ka BP *Betula nana* arrived. At about the same time *Juniperus communis* immigrated; the latter species shows a marked fall in the values for pollen percentage and pollen influx at around 4.4 ka. It is assumed that these declines are due to colder and moister summers. The last immigrant is *Alnus crispa*, which expanded rapidly, but shows a gradual decline shortly after its immigration, caused by declining summer temperatures.

In the inner parts of the Scoresby Sund region, a marked rise is seen in the *Betula nana* curve just after the species arrived at about 8.8 ka BP (Funder, 1978). It appears that dwarf birch

Figure 8 Simplified pollen diagram from Johs. Iversen Sø in the inner part of the Godthåbsfjord in southwestern Greenland. The curves show percentage values, and the bars show influx values. The sediments consist of clay in the bottom, followed by clay-gyttja, and then by ca. 3 m gyttja. Modified from Fredskild (1983).

met with little competition after it arrived. Rich dwarf shrub heaths gave way to more open heaths or fell-field vegetation during the mid- to late Holocene.

The first humans arrived in Greenland 4.5 ka BP, but these Paleo-Eskimos hardly influenced the regional vegetation. However, technological development allowed the first Europeans to colonize Greenland about 1 ka BP. The Norse settled in south and southwest Greenland, where they founded the Eastern and the Western Settlements, with around 300 farms and 20 churches. The economy was mainly based on husbandry, especially cattle, sheep and goats, but also horses and pigs. Distinct changes of the vegetation took place following the landnam (land clearance) (Fredskild, 1988). The Norsemen introduced a range of species, and *Rumex acetosella* (sheep sorrel) and *Rumex acetosa* (green sorrel) spread. *Betula* (especially tree birch) and *Salix* declined, whereas herbs expanded, reflecting widespread cutting of forest and shrubs, followed by grazing. In peat sections in the Western Settlement a layer of charcoal has been observed. This was deposited when the settlers burned the copses after the landnam. Farming and grazing led to increased soil erosion, and sand and clay were washed out into lakes. Overgrazing may have been one of the factors that led to the demise of the Norse between AD 1350 and 1400.

Development of Lake Vegetation

There are numerous lakes in Greenland, with large variation in extent, depth, and water chemistry. Most lakes are ultra-oligotrophic, but subsaline lakes occur locally (Bennike, 2000). In addition to high conductivity, the subsaline lakes are characterized by high alkalinity. These lakes are closed basins without outlets, so that salts that are transported into the lakes from the catchment become concentrated when the water evaporates.

Many lakes have become increasingly oligotrophic and acidic after they formed (Fredskild, 1992). This is presumably most pronounced in areas with acid rocks, such as gneiss and granite. Remains of water plants that prefer high conductivity are found in abundance in the first phase of the lake ontogeny, and the sediments can also contain large amounts of colonies of the green alga *Pediastrum boryanum*, which indicates high primary productivity (Figure 9). This first phase is followed by lower primary productivity and many of the macrophyte species disappear or become rare and sterile. This development reflects decreased outwash of nutrients from the drainage area.

Colonization of Greenland

It has been much debated whether the plant species in Greenland survived the last Ice Age in ice-free areas in Greenland, or if they immigrated after the last deglaciation. It has been suggested, for example, that *Betula pubescens* survived in South Greenland. Tree birch is one of the most warmth-demanding plant species in Greenland, and if it survived the last Ice Age, this would not only mean that ice-free areas were present, but also that summer temperatures were no lower than at present. Also, *Betula nana* has been proposed as an Ice Age survivor. Even though dwarf birch is far less warmth-demanding than tree birch, it also has a climatically determined northern range limit in Greenland, and from a Greenlandic point of view it cannot be considered a cold-adapted plant. Pollen analysis has shown that both species arrived during the Holocene. Iversen proposed that only the hardiest plants survived, a viewpoint followed by Fredskild.

Fieldwork in Jameson Land has resulted in finds of macroscopic remains of plants that grew there during the first

Figure 9 Strongly simplified model showing long-term changes of lakes in the area around the Godthåbsfjord in southwestern Greenland based on pollen, seeds, fruits, and leaf fragments. The plant species that prefer the highest conductivity and the most eutrophic conditions are placed to the left in the diagram.

millennium of the Holocene (Bennike et al., 1999). The oldest deposits only contain remains of a few hardy herbs and bryophytes. Most of the recorded species are presently widely distributed in Greenland, and play an increasingly larger role toward the north, but some species only found at present in the northern parts of Greenland are represented. The first woody plant that seems to have appeared is *Empetrum nigrum*, which is not especially hardy, but which has berries that are adapted to dispersal by birds. All warmth-demanding species are now believed to have immigrated after the last deglaciation. It is proposed that storms and birds, maybe often in combination, played a crucial role in long-distance chance dispersal.

With respect to macrolimnophytes, it has been concluded that the first species to arrive were species that are presently widely distributed in Greenland. More warmth-demanding species followed, and the most warmth-demanding species were the last to arrive (Fredskild, 1992).

The arrival of those plants that produce much pollen can be pinpointed rather precisely. In lake or peat sequences, the pollen curve for such a species may rise drastic, reflecting rapid expansion just after immigration. Birch species are prolific pollen producers, and from pollen analyses it has been possible to establish that *Betula nana* arrived in East Greenland at ca. 8.8 ka BP, and in West Greenland at ca. 7 ka BP. *Betula pubescens* arrived at ca. 4.2 ka BP in southern Greenland.

Possible immigration routes to Greenland can be suggested for those species that have restricted modern day geographical ranges (Figure 10). *Draba sibirica* (siberian whitlow-grass) is,

Figure 10 Map of the Earth's northern parts with arrows that show possible immigration routes to Greenland. The routes are suggested from the modern day geographical ranges of the species. The route from Labrador has played a small role, even though the distance to Greenland is fairly short. However, *Alnus crispa* and some other species probably colonized Greenland from Labrador. Even fewer plants appear to have arrived from Baffin Island. Surprisingly, many species have colonized Greenland from northwestern Europe. The distance is long, but the Faeroe Islands and Iceland form stepping stones along the route. If dispersal by birds is important, that may explain this paradox, because a large part of the Greenland migrating birds winter in Europe and Africa. A few species are considered immigrants from Siberia to East Greenland.

for example, considered an immigrant from Siberia to East Greenland. It has previously been suggested that this species immigrated to Greenland via western Siberia and northern North America. However, it is hard to understand why the populations along the migration route should die out.

Molecular data show that populations of plant species from opposite sides of the Atlantic Ocean often have identical or very similar chloroplast haplotypes, which indicates that migration rates across the Atlantic are much higher than previously envisaged by many botanists (Brochmann et al., 2003). On the basis of the genetic results it is concluded that the glacial survival hypothesis is not needed to explain the modern day distributions of plants in the Arctic. Hence, these results support the fossil evidence for postglacial colonization by the majority of the vascular plants in Greenland.

Glossary

$\delta^{13}\text{C}$: The ratio of two stable isotopes of carbon, ^{13}C and ^{12}C , reported as departures in parts per thousand from a laboratory standard. They can be used to determine the relative abundance of warm-season prairie grasses (C_4 ; $\delta^{13}\text{C}$ around -4° / in speleothems)

to other plants (mainly C_3 ; $\delta^{13}\text{C}$ around -9° / in speleothems).

Speleothem: Calcium carbonate deposits in a cave, in this case, stalagmites (columns growing upward from the cave floor).

Isotopes: Alternate forms of the same element having different numbers of neutrons in their atoms.

Introduction

The purpose of this article is to summarize research on Holocene plant macrofossils from a new or at least a little-used source, alluvial sediments in the upper reaches of small streams, in reconstructing the vegetational history of the central Midwestern United States. The focus is on the spatial and temporal establishment of upland vegetation, being principally deciduous forest, savannah, and prairie. The two most complete sites along the prairie-forest border, one in northeastern Iowa and the other in southwestern Minnesota, will be presented first and in the greatest detail. Then results are briefly described from sites in southeastern Nebraska, well into the presettlement prairie, southwestern Indiana within the presettlement deciduous forest, and along the prairie-forest border in southwestern Missouri.

Plant macrofossils were one of the most under-used, valuable paleoecological tools in North American Quaternary paleoecology. Although they were used first in the early 1900s to establish the foundations of the vegetational history of northwest Europe, their use was almost universally supplanted by pollen analysis. Arguably, the University of Minnesota has played an important role as a center for plant macrofossil research. Although some macrofossil work in Minnesota was done prior to 1950 (Rosendahl, 1948), modern work with a stratigraphic context began with the establishment of a laboratory and reference collection by HE Wright Jr. at the Limnological Research Center, University of Minnesota. Visiting scientist WA Watts, working on lake and marsh sediments, established the importance of macrofossils in paleoecology beginning in the 1960s. This tradition was carried on by John and Hilary Birks (Birks, 1980), Krystyna Wasylikowa, and Johanna and Eberhard Gröger in the late 1960s and 1970s, and by later visitors and students. The small field of macrofossil workers grew as John Matthews, Norton Miller, Stephen Jackson, Rolf Mathewes, Paul and Hazel Delcourt, Dorothy Peteet, and others established their own laboratories, trained students, and contributed substantially to macrofossil research. Recent summaries indicate that the field has matured (Birks and Birks, 2003; Jackson, et al., 1997).

Despite these additional researchers, our understanding of the Holocene vegetation of the central Midwestern United States south of the Wisconsin glacial border has lagged behind that

of glaciated terrain because typical fossiliferous sites are rare. My colleagues and I discovered that sediments in many cutbanks, in first- to third-order streams beyond the glacial border, contain a rich record of pollen and plant macrofossils (Figure 1). These remains (Tables 1 and 2) are present where the ground-water table has been consistently high, preventing oxidation of the sediments and their organic remains.

To study these sequences, at least 2–4 liters of cutbank samples are dug from, at, or near water level (or rarely cored), stored in plastic bags, and brought to the laboratory. A minimum of 200 ml is washed through screens with 0.5 and 0.1 mm mesh, and plant remains are picked from the residue using small tweezers and brushes. The various parts of plants are identified using a modern seed, fruit, and bud collection of over 3100 accessions housed in The Repository, Department of Geoscience, University of Iowa.

By choosing sample sites relatively close to the headwaters of the stream, the chances of long-distance transport by running water are eliminated. Each site represents a short period of deposition, so each is a snapshot of vegetation in the area at one time. Every site is radiocarbon-dated using well-preserved wood, or occasionally leaves or disseminated organic materials. Sampling multiple sites up and down the stream has provided a good representation of Holocene vegetation. Ages reported here have been converted to calibrated radiocarbon dates unless otherwise specified. Conversion of ages to calibrated years was based on 50% median probability and 2-sigma range and was referenced to 1950 AD using CALIB 5.0 (Stuiver et al., 2005).

The richness of the alluvial records (compare Kirchner Marsh with other sites in Tables 1 and 2) and the ability to identify many of the plant remains to species, allow much greater resolution of Holocene plant communities including aquatic, wetland, disturbed ground, forest trees, forest understory herbs, shrubs and vines, and prairie, than is possible from lake or wetland samples. Because of space limitations, only prairie and forest habitats are presented in this article. Other habitats are described in Baker et al. (1996, 1998, 2002) and Baker (2000).

Macrofossils most commonly represented are seeds and fruits, but a wide variety of other plant parts can be identified in many cases. The types of remains identified in this study are listed at the bottom of Tables 1 and 2. The units plotted on the diagrams are numbers of specimens/liter.

Figure 1 Map of Midwestern sites mentioned in the text and generalized presettlement vegetation. Short-dashed line is mid-Holocene prairie-forest ecotone.

The use of alluvial samples in reconstructing past environments has been validated in several ways:

1. Two studies compared plant remains in modern stream alluvium with the vegetation in the surrounding area. [Baker and Drake \(1994\)](#) investigated alluvial samples from a prairie preserve in northwestern Iowa, and [Strickland \(1998\)](#) examined samples from a forest stream in southeastern Minnesota. In both, the plant remains contained numerous indicators of several habitats in the surrounding vegetation.
2. Interpretation of pollen, macrofossils, and other types of fossils in several Holocene alluvial samples are compatible ([Baker et al., 1996, 2000, 2002; Work et al., 2005](#)).
3. Speleothem isotopes ([Figure 2](#)) provide a high-resolution (annual to decadal) record of events along the prairie-forest border ([Baker, et al., 1996, 2002; Denniston et al., 1999;](#)
4. [Dorale et al., 1992](#)), and $\delta^{13}\text{C}$ fluctuations in these sites indicate the same directions and timing of Holocene vegetational change. The $\delta^{18}\text{O}$ record shows changes concomitant with those in the $\delta^{13}\text{C}$ record and indicates a response to both temperature and evaporation ([Denniston et al., 1999](#)).
4. The $\delta^{13}\text{C}$ in fine-grained alluvial samples correlates well with both associated plant fossils and with a nearby speleothem isotopic record ([Baker et al., 1998](#)).

The diagrams in this article are color-coded to represent the presettlement vegetation on the map. The same colors are used on the diagrams to indicate the close correspondence between Holocene and modern communities. Blue = Late Glacial conifer forest (not shown on map), green = deciduous forest, orange = prairie, and yellow = savannah or savannah-like vegetation.

Northeastern Iowa

Roberts Creek is located in the forest, just east of the prairie-forest border in Iowa (Figure 1). Although this article focuses on the Holocene record, two sites contain Late Glacial

records. The Late Glacial at Roberts Creek (Figure 3), lasting until ~11 000 years BP, is dominated by *Picea* and *Larix* pollen, needles, and cones confirming regional trends, showing that these trees arrived at least by 13 000 years BP and were the dominant Late Glacial taxa. Although the numerous *Picea*

Figure 2 Comparison of arboreal pollen curve and speleothem records. Spring Valley cave and Kirchner Marsh are north and west, and Cold Water Cave and Roberts Creek are south and east, of a mid-Holocene forest/prairie ecotone.

Figure 3 Late Glacial and Holocene macrofossils from Roberts Creek, northeast Iowa; trees and arboreal pollen percentages of the total pollen sum.

needles and pollen were not identified to species, several cones of *P. glauca* and one of *P. mariana* were present. Macrofossils of *Salix*, *Populus*, a single *Acer* sp. fruit fragment and slightly later, *Fraxinus nigra*, indicate that some deciduous trees were present in the spruce-larch forest during the Late Glacial.

The deciduous forest phase contains macrofossils of *Ulmus americana*, *Fraxinus nigra*, *Tilia americana*, *Ostrya virginiana*, *Juglans nigra*, *Carpinus caroliniana*, and *Quercus* sp. (Figure 3). Early in this phase, the presence of *Abies balsamea* needles suggests that an early period of conifer-hardwood forest (not differentiated in the figures) may have been present. Macrofossils of shady forest-floor taxa habitats are also present (Table 2), including *Aralia racemosa*, *Ranunculus abortivus*, *Cryptotaenia canadensis*, *Claytonia* cf. *virginica*, and *Laportea canadensis*, which have seldom, if ever, been found as fossils. The combined macrofossils from trees and forest herbs indicate that closed deciduous forest was present during much of this interval. Near the top of this forested phase, macrofossils of the pioneer prairie taxa, *Monarda fistulosa*, *Rudbeckia hirta*, and *Zizia aurea* appear, while forest taxa are still abundant. These taxa are among the early dominants in modern prairie reconstructions, suggesting that they also were early migrants into forest openings that began to appear. The occurrence of *Picea* and *Larix* needle fragments is a common feature of several midwestern macrofossil sites (Watts and Winter, 1967). These are degraded tips and bases of needles that are resistant to both chemical and mechanical breakdown. Although these conifers could have persisted in the early Holocene in cool, north-facing habitats, their occurrence, their persistence well into the mid-Holocene, and their corroded appearance suggests that they are reworked.

Arboreal pollen, together with arboreal and forest-floor macrofossils, decreased sharply about 5500 years BP, as Poaceae and *Ambrosia* pollen percentages rose rapidly. A rich mix of over 20 taxa of plant macrofossils of prairie plants occurs in the orange zone and the lower part of the prairie phase (Plate 1, Figure 4). Many of these represent presently common tall-grass prairie plants in the three most important families, Poaceae

(*Sorghastrum nutans*, *Andropogon gerardii*, *Schizachyrium scoparium*, *Stipa spartea*, *Dicanthelium oligosanthos* type), Fabaceae (*Amorpha canescens*, *Dalea candida*, *D. purpurea*, *Desmodium canadense*), and Asteraceae (*Helianthus grosseserratus* type, *Rudbeckia hirta*, *Ratibida pinnata*, *Liatris aspera*). *Monarda fistulosa*, *Zizia aurea*, and *Hypoxis hirsuta* are some of the other common prairie taxa represented (Figure 4, Table 2). This diverse assemblage represents species that presently grow in dry, mesic, and wet prairies, and they give a much more complete picture of the prairie than pollen alone. (See Validation of Pollen Studies)

Two particular cutbanks are especially rich in macrofossils (Figure 4), and abundant charcoal and popped seeds indicate that fires removed the myriad of dense prairie stems, which increased runoff and facilitated transport of plant remains to these sites.

In the subsequent savannah phase, the increase in arboreal pollen percentages (Figure 2) is largely *Quercus*, which is generally poorly represented in the macrofossil record. Few macrofossils of other arboreal taxa occur in this interval, and only *Tilia* and the riparian tree *Salix* are consistently present. Only two forest-floor herbs are present near the top of the sequence, suggesting that heavily shaded habitats were rare. Prairie plants continue to be well represented during this last 3500-year period. This assemblage is consistent with an oak savannah.

The post-settlement period, the widely recognized *Ambrosia* pollen zone in North America, is represented by the youngest three samples. It shows a marked increase in numbers and diversity (at least 18 taxa) of weedy-plant macrofossils, with peaks of many alien species as well as native weeds (Baker, et al., 1993, 1996). Most of the macrofossils representing other habitats declined or disappeared in the historical period. Non-native insects also appear in the post-settlement sediments, and the sediments indicate rapid runoff and soil erosion (Baker et al., 1993). These changes mesh well with the historical record of deforestation and cultivation of crops, indicating that the stream cutbanks and their macrofossil assemblages also record changes in human land-use practices.

The high-resolution carbon isotopic record from Coldwater Cave (Figures 1 and 2) fills in the gaps in the alluvial record and supports the conclusions. The carbon isotopic record shows $\delta^{13}\text{C}$ values between -8 and -9 , indicating a strong C_3 -dominated vegetation for the forest from 9000 to 6000 years BP. Beginning about 6000 years BP, the $\delta^{13}\text{C}$ values increased gradually to -5.5 by 3000 years BP. This gradual buildup marks the slow accumulation of organic carbon in the soil over the cave of $\delta^{13}\text{C}$ from C_4 grasses that are dominant in the prairie and present at Roberts Creek. The large fluctuations may indicate periodic droughts similar to those recorded in the ratios of aquatic plants to weeds in the macrofossil record at Kirchner Marsh (Watts and Winter, 1967). The re-establishment of some trees in savannah is indicated by the return of $\delta^{13}\text{C}$ values to -7 to -8 after 3000 years BP.

Plate 1 Prairie-plant macrofossils and modern reference specimens. Fossils are all from Roberts Creek, northeast Iowa. 1-Fossil *Amorpha canescens* pod, 2-Fossil *Amphicarpaea bracteata* pod, 3-Fossil *Dalea candida* calyx, 4-Fossil *Hypoxis hirsuta* seed, 5-Modern *Silphium laciniatum* fruit, 6-Fossil *Silphium laciniatum* fruit, 7-Fossil (left) and modern (right) *Ratibida pinnata* fruits, 8-Modern (left) and fossils (right) of *Rudbeckia hirta* fruit, and 9-Modern (left) and fossil (right) of *Liatris aspera* fruit. Bar is 1 mm long.

Southeastern Minnesota

A Late Glacial record is also present at Money Creek and Pine Creek (hereafter simply referred to as Money Creek), which are also in the deciduous forest at present. It is similar to that at

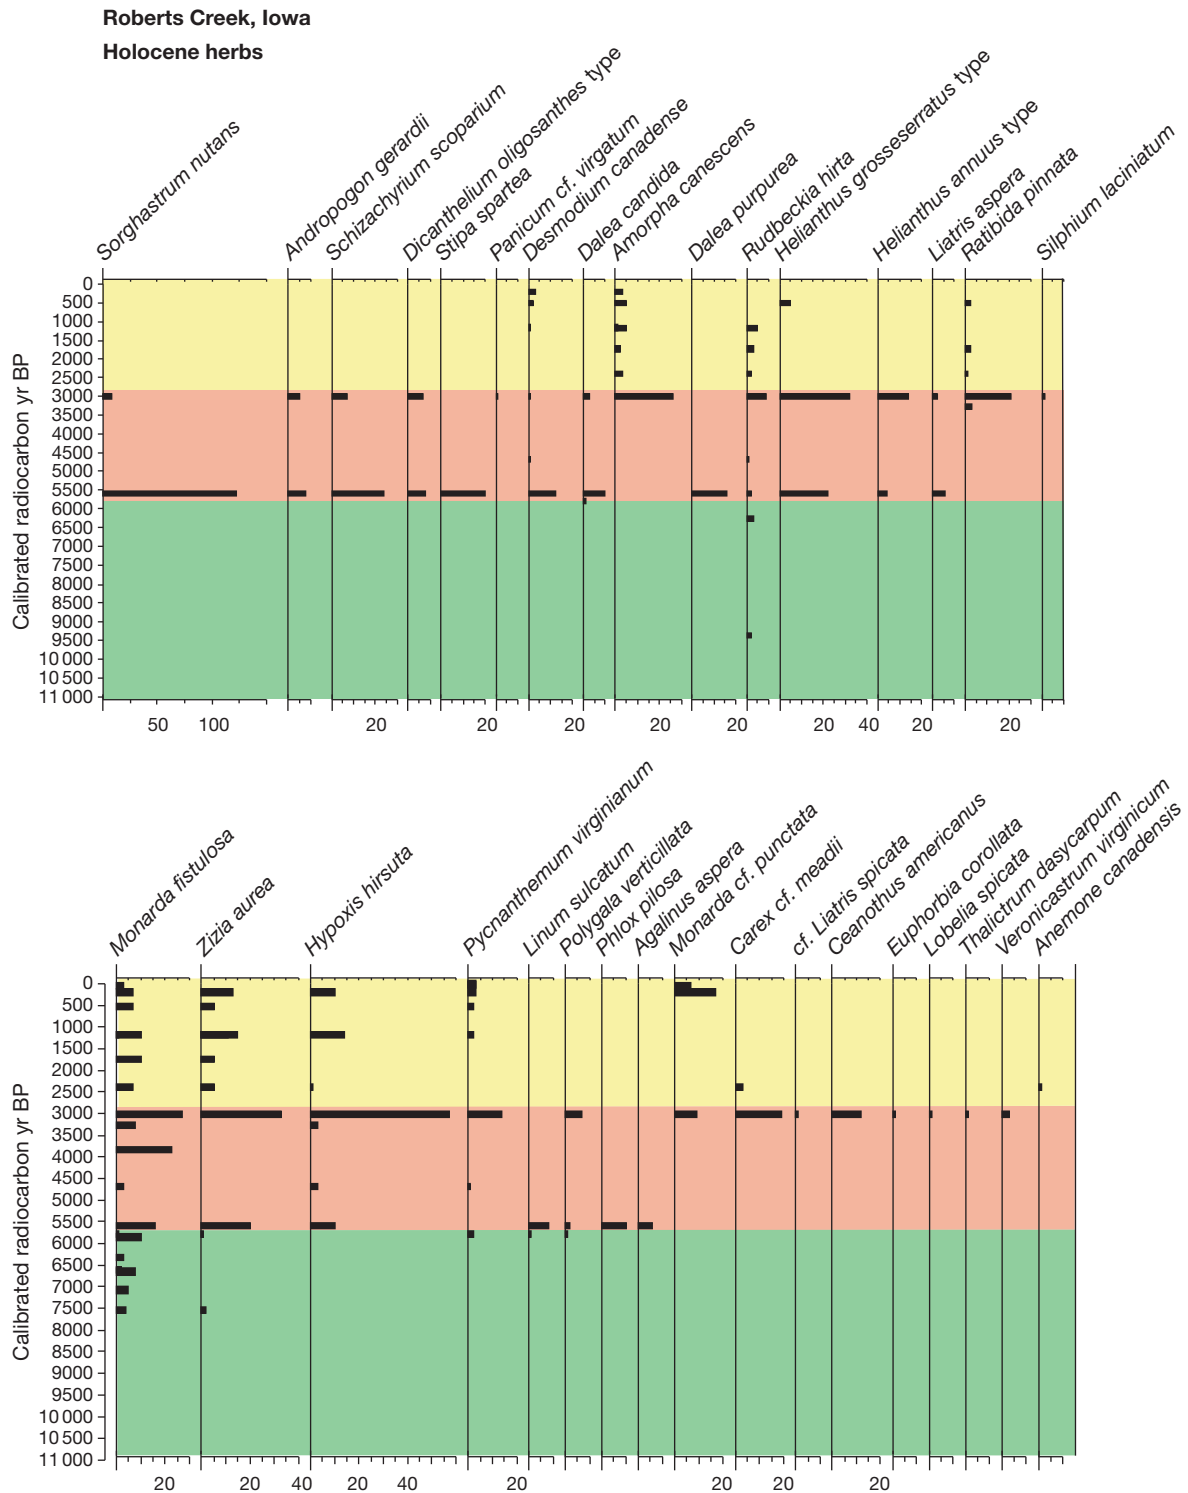

Figure 4 Holocene macrofossils from Roberts Creek, northeast Iowa; prairie plants.

Roberts Creek, except for the occurrence of the sub-Arctic species *Selaginella selaginoides* and *Betula nana* (= *B. glandulosa*). *Picea mariana*, *Larix laricina*, *Populus* sp., *Salix* sp., and *Tilia* were present at Money Creek about 13 000 years BP (Figure 5). The deciduous elements are not abundant, but their occurrence indicates at least a scattered presence in Late Glacial forests.

Although there are significant gaps in the Late Glacial record from about 13 000 to 9700 years BP and in the early Holocene record from 9500 to about 7400 years BP (Baker et al., 2001, 2002), there are close similarities to the Roberts Creek sequence. The early Holocene samples contain *Tilia americana*, *Ulmus americana*, *Carpinus caroliniana*, *Ostrya*

Figure 5 Late Glacial and Holocene macrofossils from Money Creek, southeast Minnesota; trees and arboreal pollen percentages of the total pollen sum.

virginiana, and *Quercus cf. macrocarpa* (Figure 5). In addition, a similar suite of shady forest-floor understory herbs occurs in the deciduous-forest phase, including *Aralia racemosa*, *Laportea canadensis*, and *Campanula americana*. *Monarda fistulosa*, *Heliopsis helianthoides*, and *Helianthus grosseserratus* type, which are pioneer prairie taxa, are present as early as 8300 years BP, suggesting that, as at Roberts Creek, these plants became established in forest openings before the arrival of prairie.

All deciduous forest taxa disappear around 5500 years BP, and arboreal pollen percentages drop precipitously (Figures 5 and 6). Macrofossils of the important tall-grass prairie grasses, *Schizachyrium scoparium* and *Sorghastrum nutans* appear, followed by *Helianthus laetiflorus* type, *Amorpha canescens*, *Andropogon gerardii*, *Desmodium canadense*, *Pycnanthemum* sp., *Rudbeckia hirta*, *Dalea candida*, and *Zizia aptera* (Figure 6). As at Roberts Creek, these taxa and the disappearance of tree taxa indicate that a diverse mesic tall-grass prairie was well established. The dominant prairie-plant families, Poaceae, Fabaceae, and Asteraceae, are also well represented here by plant macrofossils.

After about 3500 year BP, the abundance and diversity of prairie-plant macrofossils decreases, arboreal pollen percentages rebound, especially *Quercus*, and macrofossils of several deciduous trees reappear (Figure 5). Several prairie-plant macrofossils continue to be present, suggesting that oak savannah was established, with prairie growing in open areas between the widely spaced oaks (Figure 6). The tall grasses (*Sorghastrum*, *Schizachyrium*, and *Andropogon*) were not found in the savannah phase. These grasses provide substantial biomass to fuel fires; if they were poorly represented, it could be that fires may have been less frequent and/or not as hot, perhaps allowing the development of the savannah oaks, at least in some areas. Post-settlement samples record a sharp increase of 16 taxa of weedy disturbance plants (Baker et al., 1993). Most of the remains of native vegetation of all habitats disappear from the record.

In contrast to the above sequence, Kirchner Marsh, also along the presettlement prairie-forest ecotone, remained in prairie throughout the mid-Holocene (Watts and Wright, 1967; Wright et al., 1963). There, tree pollen declined sharply about 9000 years BP, as prairie taxa begin to arrive (Figure 2). Prairie was well established by 8000 years BP, and was dominant until about 3000 years BP. Although this marsh/lake sequence provided little macrofossil evidence of upland vegetation, the wetland and aquatic seeds combined with the generally upland pollen assemblage still provided a reasonable reconstruction of Holocene climatic and vegetational change. A stalagmite from Spring Valley Cave (Denniston et al., 1999), west of the ecotone (Figure 1), shows a sharp change in $\delta^{13}\text{C}$ (solid line), indicating a change from C_3 to C_4 grasses about 8000 years BP, reverting to C_3 plants about 3000 years BP. Baker et al. (1992) suggest that dominant presence of dry air from the Pacific moved eastward across northern and central Minnesota between 9000 and 8000 radiocarbon years BP, but was blocked by warm, moist air from the Gulf of Mexico in eastern Iowa and southeastern Minnesota. These sequences indicate that the mid-Holocene advance of prairie across southern Minnesota, as in Iowa, stalled along a sharp prairie-forest ecotone for at least 2500 years BP (Figure 1).

Southeastern Nebraska

Sites along the South Fork of the Nemaha River in Nebraska, well within the presettlement tall-grass prairie, have yielded a relatively complete Holocene record for about the last 9000 years BP (Baker, 2000; Baker et al., 2000). The early Holocene phase with forest elements is present from about 9000 to 8500 radiocarbon years BP. It contains macrofossils of deciduous trees including *Ulmus americana*, *U. rubra*, *Juglans cinerea* type, *Juglans nigra*, *Carya cordiformis*, *Carya ovata*,

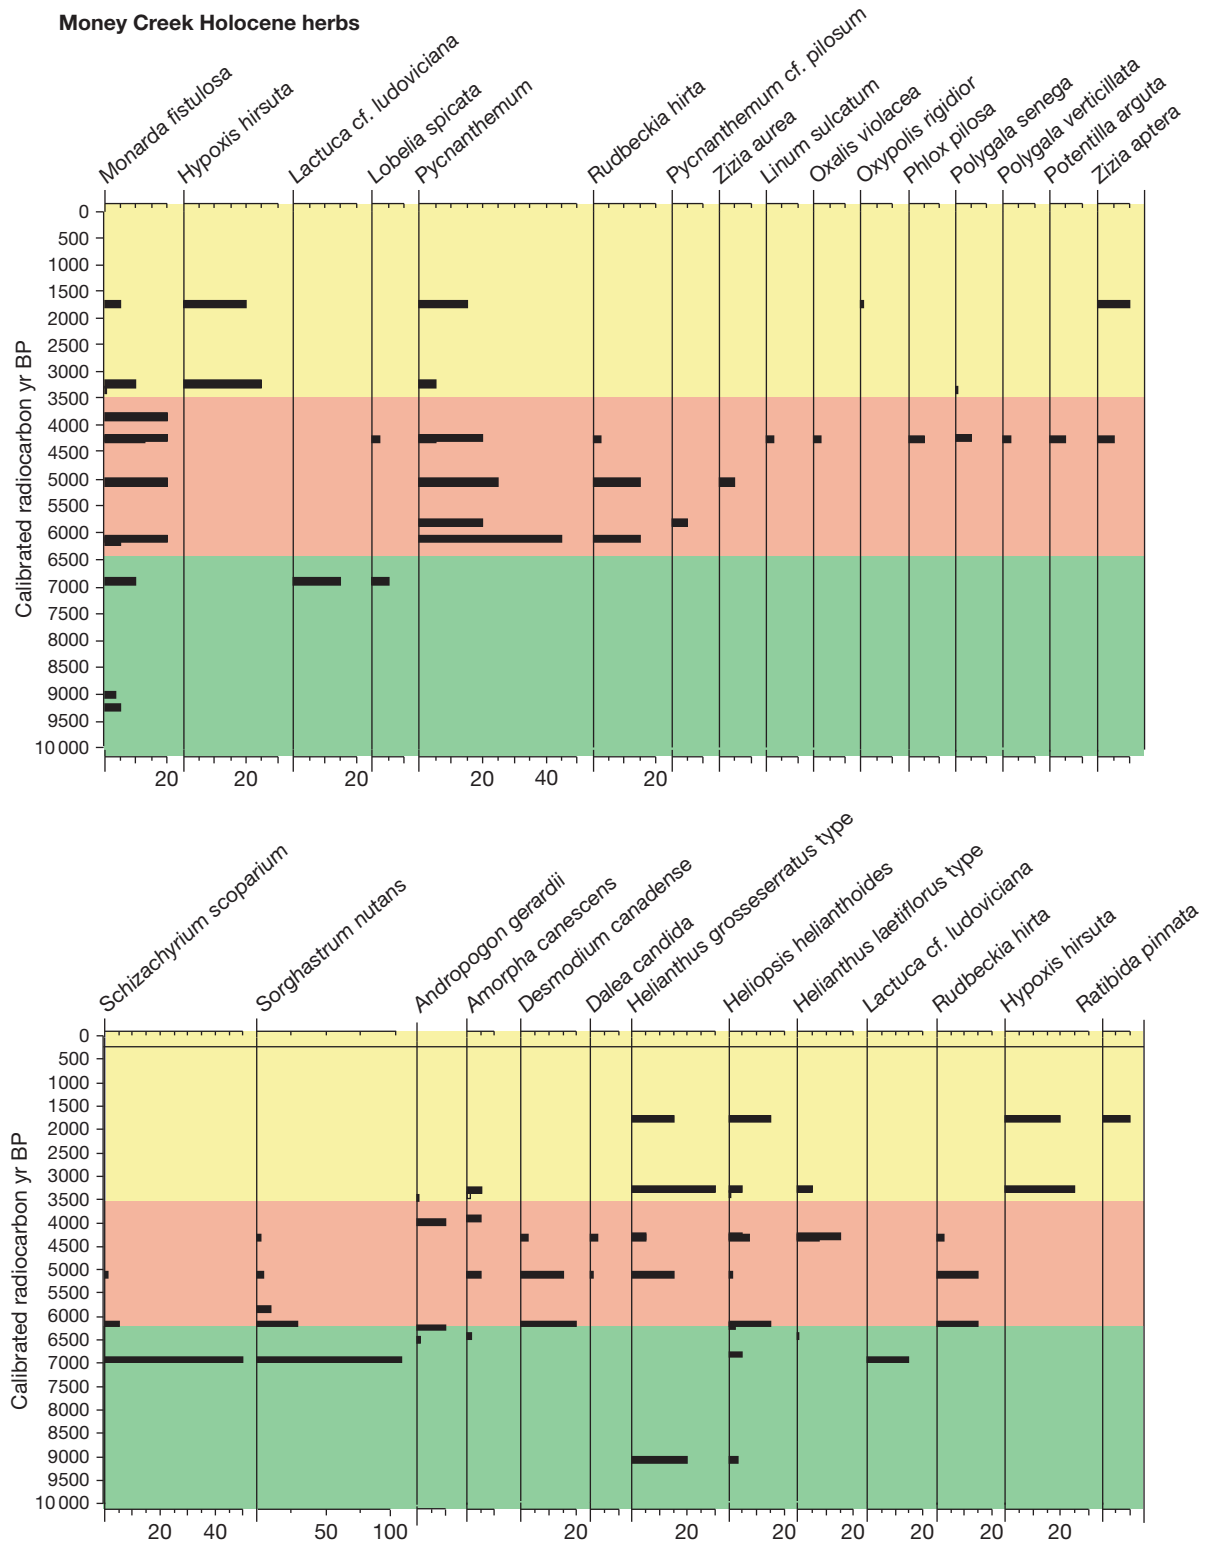

Figure 6 Holocene macrofossils from Money Creek, southeast Minnesota; prairie plants.

Figure 7 Holocene macrofossils from Nemaha River, southeast Nebraska; upland trees.

Fraxinus americana, *Ostrya virginiana*, *Quercus macrocarpa* type, and *Tilia americana* (Figure 7). These suggest that an upland deciduous forest was present during this part of the early Holocene. Several riparian trees, including *Acer negundo*, *Morus rubra*, and *Salix exigua* ssp. *interior*, indicate that riparian forest was also present (Baker, 2000). A limited forest understory assemblage of *Campanula americana*, *Laportea canadensis*, *Salvia lyrata*, and *Sanicula gregaria* indicates that at least some closed forest was present. The low numbers and diversity suggest that the shady understory habitat was less extensive than at the sites in Minnesota and Iowa. Also, the prairie species *Andropogon gerardii*, *Schizachyrium scoparium*, *Sorghastrum nutans*, *Sporobolus asper*, *Stipa spartea*, *Amorpha canescens*, and *Helianthus x laetiflorus* type (Figure 8), along with low arboreal pollen percentages and prairie phytoliths (Baker et al., 2000), indicate that prairie openings were extensive during this interval. It is likely that the upland deciduous trees grew in copses on mesic sites along the valley sides, and prairie grew on the uplands and in dry sandy soils, constituting a savannah-like habitat.

During the rest of the Holocene in Nebraska (Figures 7 and 8), except for the drought tolerant oaks, the upland trees disappeared, but riparian trees, including *Ulmus* spp., persisted throughout most of the last 9500 years BP. Prairie elements are abundant and diverse throughout. The prairie taxa mentioned above generally increase in numbers and other taxa are sporadically present. A particular short interval occurred from 3300–2900 years BP, when the grasses *Andropogon*, *Schizachyrium*, and *Sorghastrum* along with *Helianthus x laetiflorus* type are particularly abundant, other species like *Dalea candida*, *Lespedeza capitata*, *Desmodium canadense*, *Helianthus grosseserratus* type, and *Heliopsis helianthoides* make a showing, and even riparian-tree macrofossils disappear.

This interval also has a sharp peak in $\delta^{13}\text{C}$ values, indicating greater input of C_4 grasses (Baker et al., 2000). The importance of *Andropogon*, *Schizachyrium*, and *Sorghastrum* along with *Amorpha canescens*, suggests that this may represent a dry period. They have deep root systems and were hardly affected by drought in the 1930s (Weaver, 1968). In any event, it appears that the middle and late Holocene were dominated by prairie.

The record of post-settlement time is not rich, and the abundance of bud scales of *Ulmus americana* and *U. rubra*, and leaf-lobes of either *Quercus alba* or *Q. macrocarpa* suggest that a savannah-like environment may have become established, possibly caused by the cessation of fire after settlement.

Southwestern Indiana

Limited work in southwestern Indiana, well within deciduous forest, has resulted in only nine dated intervals (Figure 9). There are large gaps in time, but critical times are covered sufficiently to give an outline of the Holocene vegetational history.

The early Holocene has the most diverse macrofossil record of trees. *Ulmus americana*, *Carpinus caroliniana*, *Morus rubra*, and *Platanus occidentalis* have multiple occurrences and are abundant in at least some localities. Trees of southeastern or eastern distribution that occur only in the Indiana sites are *Liquidambar styraciflua*, *Fagus grandifolia*, and *Liriodendron tulipifera*. These appear in the early Holocene, but only *Liriodendron* occurs in the middle to late Holocene (where samples are few and widely spaced). Forest understory herbs that occur sporadically are *Aralia racemosa*, *Campanula americana*, *Carex backii* type, *Claytonia virginica* type, cf. *Cryptotaenia canadensis*,

Nemaha River, Nebraska
Holocene herbs

Figure 8 Holocene macrofossils from Nemaha River, Nebraska; prairie plants.

Eupatorium cf. rugosum, *Laportea canadensis*, and *Ranunculus abortivus*. Three species that could represent prairies, *Helianthus helianthoides*, *Monarda fistulosa*, and *Thalictrum dasycarpum* (not shown), all occur at 3830 years BP. From this imperfect record, the vegetation in southwestern Indiana appears to have been forested throughout the Holocene. The only evidence of some

open areas is the occurrence of the three facultative prairie species, but the absence of any of the prairie grasses or other characteristic prairie taxa, and the fact that these three species can also occur in open woodlands, suggests that prairie was not extensive, and probably was not present in this part of Indiana.

Figure 9 Holocene macrofossils from Indiana; trees.

Sac River, Missouri

Figure 10 Holocene macrofossils from Sac River, Missouri; trees.

Sac River herbs

Figure 11 Holocene macrofossils from Sac River Missouri; prairie plants.

Southwestern Missouri

Preliminary work along the Sac River, southwestern Missouri (Baker et al., 2005), has yielded a complete early Holocene record (~9000 to ~5000 years BP), but a very large gap (~5000 to ~1800 years BP) exists in the late Holocene (Figures 10 and 11). The sites are located in the deciduous forest close to the southern limb of the prairie-forest border (Figure 1) and thus should be as sensitive as the Minnesota and Iowa sites, where dramatic shifts of the prairie-forest border occurred.

Only *Ulmus americana*, *Salix* sp., and *Platanus occidentalis* are present in the oldest sample (9000 years BP). By about 7000 years BP, the probable upland trees, *Quercus* (subgenus *leucobalanus*-white oak group), *Juniperus virginiana* type, and cf. *Acer saccharum* become abundant. By about 5500 years BP, the full suite of trees is present including the bottomland tree, *Betula nigra* and shrub, *Alnus serrulata*. Most of these species are also present in the latest Holocene above the gap (Figure 10).

No prairie plants were present at 9000 years BP, but between 8000 and 8500, the tall prairie grasses *Andropogon gerardii*, *Schizachyrium scoparium*, and *Sorghastrum nutans* appear along with the prairie legume, *Dalea candida* (Figure 11). By about 7000 years BP, a full suite of prairie species are present, but by the late Holocene, most of the prairie species have disappeared. It appears that the prairie-forest border was close to its present position throughout the early Holocene. There appear to be no large swings toward either prairie or forest during the period of coverage. The pollen record by Moss also suggests no major shift in the prairie-forest border (Baker et al., 2005). The late Holocene looks to have been relatively forested, perhaps with a few openings. It is possible that major shifts occurred during the late Holocene gap.

Reconstruction of the Prairie-Forest Ecotone

1. The sequences in northeastern Iowa and southeastern Minnesota are similar, with a deciduous forest in the early Holocene, rapid change to diverse dry to mesic prairie about 5500 years BP, and a gradual change to oak savannah about 3000 years BP. The timing of these changes contrasts with sites in southeastern Minnesota a short distance north and west, where prairie arrived about 2500–3000 years earlier. A stable mid-Holocene ecotone between prairie on the west and forest on the east is postulated from about 8000–5500 years BP.
2. In sites within the prairie in eastern Nebraska, prairie replaced mixed open and closed forest about 9000 years BP, with relatively minor shifts in prairie types thereafter. Riparian forests were present throughout, except for a short interval from 3300–2900 years BP, which could represent a drier period.
3. Southwestern Indiana was apparently forested throughout the Holocene, including trees that are mainly eastern or southeastern in distribution. A slightly drier period with more forest openings about 3800 years BP is possible.
4. Southwestern Missouri supported both prairie and forest species in an open forest or savannah environment

throughout the early Holocene, apparently with no significant movement of the prairie forest border.

5. These records demonstrate that a strong contrast existed in the Holocene history of the southern and northern limb of the prairie-forest border. Major shifts from forest to prairie occurred in northern sites. Although there is presently a gap in coverage of middle to late Holocene, it appears that the prairie-forest border in the south was relatively stable.
6. The apparently sudden shift to prairie in southeastern Minnesota and northeastern Iowa was preceded by the establishment of a few pioneer prairie species in forest openings. The rapid disappearance of trees and establishment of many prairie species represents the demise of the forest and the establishment of the tall-grass prairie, heralded by several species in the dominant families Asteraceae, Fabaceae, and Poaceae.
7. The use of macrofossils from rarely studied river-alluvium, supplemented by pollen and stable isotope analyses, have demonstrated previously undetected phytogeographic changes in forest-prairie distribution that varied considerably in relative position throughout the Holocene in the American Midwest. The identification of macrofossils to species level has allowed an impressively detailed reconstruction of vegetation and habitats in areas where a pollen record would be extremely general and much less informative.

Abiotic and biotic variables can reflect ecological processes and their changes on several temporal and spatial scales. The reconstruction of environmental changes in the Late Glacial period is of special interest because the changes in climate and hence in climate-dependent responses of these variables were both rapid and of large amplitude.

Organisms and environmental gradients show interesting relationships. Therefore, biostratigraphies providing qualitative and quantitative changes of taxa are time series of the behavior of various types of organisms and also of environmental change. Generally, species show responses to ecological gradients by exhibiting optima and tolerances that reflect population size or productivity or some other measure of fitness. They are often unimodal. We use three examples to illustrate how these relationships can be reconstructed in three different ways: qualitative reconstruction of past environmental changes; quantitative reconstruction of past climatic changes; and estimation of the biotic response to climate change, which is possible only if an independent line of evidence for the climate change is available.

Time control is essential for all estimates of rates of change. However, in the Late Glacial period (ca. 16 000–11 500 cal yr BP) time control can be hampered by (1) the absence of organic material suitable for radiocarbon dating, (2) the presence of reworked organic material, (3) plateaus of constant radiocarbon ages, and (4) problems of calibrating the radiocarbon time-scale. Dating techniques other than radiocarbon (e.g., several geophysical techniques) may have large errors or are applicable only at special sites (e.g., annual sediment layers or varves).

Among terrestrial ecosystems, the vegetation (i.e., the primary producers) may provide the best reconstruction of the past climate. Aquatic ecosystems may be of special interest because water plants and aquatic invertebrates (e.g., insects or Cladocera) can respond rapidly to climatic warming or cooling for at least three reasons: Their dispersal of propagules (seeds, fruits, resting stages, or adults) may be fast because of the high mobility of the main vector (e.g., water fowl); their life cycles are relatively short; and they have no special requirements, such as mature soils.

The complementarity of pollen and plant macrofossil analyses may be especially useful for the reconstruction of past environments. Identification of plant macrofossils can often go to the species level (instead of only the genus or family level; see the example of dwarf birch and tree birches), and local presence can be assumed if heavy macroremains are found, whereas pollen may be more easily transported from a long distance. Both aspects may apply to terrestrial and aquatic plants.

Qualitative Reconstruction of Past Environments

Multidisciplinary studies are most precise if all analyses can be made on a single core. Some studies, however, need relatively large volumes of sediment per sample (e.g., beetle analysis); in such cases, several cores and their correlation may be needed. Alternatively, open exposures may provide large sample volumes. Beetles may offer additional information, such as habitat structure or openness of vegetation.

We present two examples of the qualitative reconstruction of past Late Glacial environments, one indicating primarily changes in temperatures and the other indicating changes in both effective moisture (lake level) and temperature.

The Late Glacial in Switzerland

The biostratigraphic changes during the Late Glacial on the Swiss Plateau (the lowland between the Jura Mountains and the Alps) are summarized in [Figure 1](#) and [Table 1](#). Two phases of strong and rapid warming occur at approximately 14 500 and 11 500 cal yr BP (i.e., at the beginning of the Bølling and beginning of the Holocene). They reflect global or hemispheric pulses of climatic warming. The Oldest Dryas on the Swiss Plateau can usually be subdivided into three phases. At the base, the pollen concentration is low, plant macroremains are absent, and many reworked pollen grains are present, indicating the dominance of open ground and scarce vegetation after deglaciation. The second phase reflects a species-rich steppe–tundra (sometimes subdivided into two subphases) ([Caillard, 1984](#)). Then a marked increase in the birch pollen curve can be attributed to a higher abundance of dwarf birch (*Betula nana*); the species identification is based primarily on plant macrofossils (a few remains of tree birches are also found). The sharpest transition for the entire Late Glacial occurs at approximately 14 500 cal yr BP at the beginning of the Late Glacial interstadial (Bølling). The plant macrofossils show a change from dominant dwarf birch to dominant tree birch (the last remains of dwarf birch are found within the *Juniperus*–*Hippophaë* regional pollen zone; the Linnean species *Betula 'alba'* includes several species of tree birches). At the same time as this ecologically important period of afforestation, the assemblages of all groups of aquatic organisms change ([Figure 1](#)). Most inferences of biotic changes involve steps in climate warming (and cooling at the beginning of the Younger Dryas). However, related, climate-induced conditions are important, such as pedogenesis, trophic state, and seasonal circulation patterns in lakes (affecting oxygen conditions). The forested Late Glacial is first dominated by tree birches (Bølling) and then by pine and tree birches (Allerød). Minor fluctuations within this Late Glacial interstadial can only be traced if the sites

Figure 1 Overview of bio- and isotope stratigraphies of the Late Glacial on the Swiss Plateau. Ecologically, the most remarkable change from the shrub-tundra in the Oldest Dryas to a juniper-birch forest in the early Bølling (i.e., a shift in dominance from dwarf birches to tree birches) coincides with the rapid shift in oxygen isotopes of at least 3 around 14 500 cal yr BP. It is accompanied by changes in the assemblages of insects (chironomids, Chaoborus, Coleoptera, and Trichoptera) and Cladocera as well as a change in abundances among mollusks. The subdivision of the Oldest Dryas based on pollen and plant macrofossils (see text for details) is also reflected in the biostratigraphies of the invertebrates: First occurrences coincide with the stepwise development of the vegetation. The rapid cooling at the beginning and the rapid warming at the end of the Younger Dryas are recorded in the oxygen isotope ratios and all biostratigraphies. Data from Ammann (1989), Gaillard (1984, 1994), Lotter et al. (1992), and Richoz (1997); the references for Lobsigensee are given in Table 1.

are at sensitive altitudes and if the sampling resolution is sufficiently high. The Younger Dryas cool period is reflected in the lowland by an opening of the forests, when heliophilous taxa such as *Larix* and *Populus* are recorded as plant macrofossils, as well as pollen of *Artemisia* and *Ephedra*. At higher altitudes, a lowering of the timberline was registered.

The Pleniglacial and Late Glacial in Lake Zeribar, Zagros Mountains, Iran

Paleoecological changes between ca. 18 000 and 6000 cal yr BP in the Mediterranean climate area of western Iran are illustrated by different proxy data obtained from a single sediment core from Lake Zeribar, Zagros Mountains, Iran (Figure 2). A pollen diagram (van Zeist and Bottema, 1977) illustrates the dominance of *Artemisia*-Chenopodiaceae steppe-like vegetation in the Pleniglacial and Late Glacial until ca. 12 000 cal yr BP. Trees were absent or limited to a few sheltered places until ca. 15 400 cal yr BP (Heinrich 1 cool oscillation). Their number increased slightly in the Bølling/Allerød interstadial, but it was reduced again during the Younger Dryas stadial. A slight increase in humidity approximately 12 000 cal yr BP favored the expansion of Poaceae-

dominated steppe-like vegetation, but the climate was still too dry for an extensive spread of trees. Until approximately 7000 cal yr BP, the drought-resistant *Pistacia* was the major tree; between ca. 7000 and 6000 cal yr BP the climate became sufficiently humid for oak woodland to become established.

Evidence of fluctuations in water levels and in salinity is obtained from various proxies in the lake (Figure 2). In the macrofossil record (Wasylikowa, 2005), peaks of *Chenopodium rubrum*, which typically expands on seasonally exposed lake-shores, indicate episodes of fluctuating and/or low lake water levels. Two cold episodes (Heinrich 1 and Younger Dryas) were also characterized by increased salinity, as indicated by the presence of halophytic macrophytes, *Ruppia maritima*, *Salicornia europaea*, and *Suaeda* sp. (Wasylikowa 2005); by peaks of brackish water and marine diatoms (Figure 2; Wasylikowa et al., 2006); and by high conductivity values (Snyder et al., 2001). Among the submerged aquatics, *Potamogeton pectinatus* expanded. It tolerates brackish water. It can also withstand short-lasting emergence and it became abundant at the same time as *C. rubrum* (Wasylikowa, 2005). The cause of the lower lake levels was probably dry climate, as indicated by elevated $\delta^{18}\text{O}$ values (Stevens et al., 2001). Higher lake water levels

during the Bølling/Allerød interstadial are indicated by the disappearance of *C. rubrum* and the spread of *Najas marina*, which tolerates brackish conditions but, unlike *P. pectinatus*, is sensitive to desiccation. A slight increase in temperature is suggested by the appearance of *Ceratophyllum demersum*, a relatively thermophilous aquatic species. In the Holocene, a series of low lake level episodes occurred between ca. 10 000 and 6300 cal yr BP, but unlike the earlier episodes, the water was fresh and salinity indicators were absent. The curve of the noncombustible mineral fraction in the loss-on-ignition diagram indicates that this was the time of intensified catchment erosion ([Stevens et al., 2001](#)). The replacement of the dominant *Najas marina* by *N. minor* approximately 11 000 cal yr BP could reflect the increase in temperature and decline of salinity.

Quantitative Reconstruction of Climate Change in the Late Glacial: The Role of Plant Macrofossils

Analog or Indicator Species Approaches

If the ecological and environmental tolerances of a taxon are well-known, either through observation or experiment, the

past ecological and environmental conditions can be inferred if the taxon is found as a fossil or subfossil; it can thus be used as an indicator species. Similarly, the environmental tolerances of an assemblage can be inferred from a modern analogue; the analog assemblage approach applies particularly well to vegetation reconstruction. If types of vegetation can be reconstructed from fossil plant assemblages, past habitats and past temperature and humidity can be reconstructed. Plant macrofossils are well suited to the analogue approach to environmental and climatic reconstruction. Past vegetation can be reconstructed in some detail, mainly because of the rather local deposition of plant macrofossils and the possibility of identifying many plant macrofossils to a detailed taxonomic level, often to species.

When pollen data were used to reconstruct the spatial and temporal distribution of vegetation types and the ecotones between them in the Late Glacial of western Norway ([Birks, 1994](#)), a southern and western distribution of birch trees was inferred during the interstadial. The ability of macrofossils to refine pollen data was then used to distinguish between tree birch (e.g., *Betula pubescens*) and dwarf birch (*B. nana*). The macrofossil record indicated that the Late Glacial interstadial of western Norway lacked birch trees. All the *Betula* pollen was derived from trees to the south by long-distance transport, or it came from *B. nana*, which was shown by macrofossil records to be present in some abundance inland but absent along the Norwegian coast ([Birks, 2003](#)). Therefore, temperature and ecotone reconstructions made on the basis of the pollen-inferred occurrence of tree birch had to be revised. Late Glacial assemblages of plant macrofossils in western Norway closely resemble the modern sub-Alpine and Alpine vegetation. The mean July temperature ranges of these modern vegetation zones are known and can thus be inferred for the past. The new interpretations are supported by the entire macrofossil assemblages, which indicate a treeless low-Alpine or mid-Alpine vegetation ([Birks, 1993, 2003](#)).

A special case of the analog approach is the mutual climate range method, used especially with Coleoptera data. By overlapping the modern climate ranges of species within a fossil assemblage, the most likely climate envelope for that assemblage is narrowed down. This approach has been applied with greater mathematical rigor to plant assemblages, particularly macrofossil assemblages with species determinations (probability density functions) ([Kühl et al., 2002](#)). It has not been applied to Late Glacial plant assemblages, but it shows promise as an alternative approach to modern analogs and transfer functions.

Multivariate Approach to Climate Reconstruction

This approach to climate reconstruction involves the use of large modern data sets of organisms that are related to their present environment by a transfer function. The transfer function is applied to fossil data to reconstruct past environments and climates. In the Late Glacial, climate transfer functions are most often used to reconstruct mean July (T_{jul}) or summer temperatures. They have been applied in Late Glacial studies in North America ([Levesque et al., 1994](#)) and Europe ([Lotter, 2000](#); [Brooks and Birks, 2000](#)).

Figure 2 Multiproxy evidence of environmental change at Lake Zeribar, Iran. Yellow zones indicate the episodes of low and fluctuating lake levels.

Temperature Reconstructions in the Late Glacial at Kråkenes, Western Norway: An Example of a Multiproxy Climate Reconstruction

At Kråkenes, western Norway, all of the previously discussed approaches were applied to several data sets from the same Late Glacial sediment core to reconstruct mean July temperature (T_{jul}). The transfer function approach was used on pollen, chironomid, and Cladocera data; the MCR method was applied to the Coleoptera data (but the data were too sparse to make a continuous curve); and the analog approach was used on the plant macrofossil data. The results are compared in **Figure 3** (Birks and Ammann, 2000).

The shapes of the temperature curves are all similar. The Allerød interstadial temperatures were cool, ca. 3–6 °C below the present T_{jul} . All the proxies show a decrease into the Younger Dryas of 1 or 2 °C. This small decrease, probably combined with increased precipitation and snow accumulation in the cirque behind the lake, was sufficient to lead to the formation and advance of a cirque glacier that drained directly into the lake, forming glaciolacustrine sediments. The proxies all show a rapid temperature rise into the early Holocene, reaching modern temperatures after approximately 1000 years (**Figure 3**).

A more detailed comparison of the results in **Figure 3** shows that the absolute temperature values differ between

proxies. The transfer function reconstructions (pollen, chironomids, and Cladocera) differ largely because of features of the modern data sets. Modern pollen assemblages from arctic or alpine situations contain long-distance transported pollen of trees with high pollen productivity and dispersal (*Betula*, *Pinus*, and *Alnus*) that was largely absent in the Late Glacial. Modern chironomid assemblages have lower taxonomic diversity below approximately 9 °C T_{jul} (e.g., on Svalbard) and therefore cannot easily differentiate cold temperatures. The cladoceran modern data set was compiled for Switzerland, where the reconstructions from Cladocera showed overall higher temperature (Birks and Ammann, 2000). The analog reconstructions from the plant macrofossil data are probably the most reliable, although they are ranges rather than single values for each sample, representing the ranges of the low Alpine (10–7.5 °C), the mid-Alpine (7.5–5 °C), and the high Alpine (<5 °C) vegetation zones of today.

The vegetation reconstructions from the macrofossil data are clear; all taxa conform to the proposed modern analog, and none disagrees. Within each vegetation zone, communities can be differentiated—for example, those related to snow beds or winter exposure, snow meltwater flushes, unstable stony ground, grassland, and dwarf-shrub heath. These mosaics also conform to present-day vegetation community mosaics

Figure 3 Comparison of mean July air temperature reconstructions at Kråkenes, western Norway. Pollen, chironomids, and Cladocera reconstructions were made with transfer functions. Coleoptera reconstructions were made with the MCR method. The plant macrofossil reconstructions were made by comparison with modern analog assemblages. From Birks HH, and Ammann B (2000) Two terrestrial records of rapid climatic change during the glacial–Holocene transition (14 000–9 000 calendar years B.P.) from Europe. *Proceedings of the National Academy of Sciences, USA* 97: 1390–1394.

in the Alpine zones of western Norway. Mosses contributed to these reconstructions (Jonsgard and Birks, 1995), and terrestrial oribatid mites were also valuable habitat indicators (Solhøy and Solhøy, 2000).

Timing and rates of climate changes at Kråkenes

Terrestrial plant macrofossils, mostly *Salix herbacea* leaves, were used to obtain a high-resolution series of AMS ^{14}C dates between 12 700 and 10 000 ^{14}C BP. A calendar-year chronology for the upper Late Glacial and early Holocene was reconstructed by wiggle matching against the Hohenheim tree-ring data that dated the Younger Dryas–Holocene transition to 11 530 $\pm$ 40/–60 cal yr BP (Gulliksen et al., 1998). In the older Late Glacial, a calendar chronology was constructed by comparison with

^{14}C -dated laminated lake sediment series. Rates of change could then be calculated for the various groups of organisms (Birks et al., 2000). The rates of T_{jul} change shown in Figure 3 are summarized in Table 2. All the proxies show a rate of decrease from Allerød to Younger Dryas of 0.7–1 °C per 25 years. Although the actual temperature drop was small, it occurred very rapidly. The rate of temperature change during the first 500 years of the Holocene was 0.2–0.3 °C per 25 years. After the initial very rapid responses to the Holocene temperature rise, rates of change decreased as communities and soils developed and internal successional processes started, thus reducing the sensitivity of the ecosystem to large temperature changes (Birks et al., 2000). These results all hinge on the use of terrestrial plant macrofossils to obtain a high-resolution series of radiocarbon dates.

Biotic Response to Climate Change

The Concept

Two conditions need to be fulfilled if the estimation of biotic responses to climate change is the goal: Some independent line of evidence for climatic change is needed to avoid circular reasoning, and the temporal resolution must be high enough to capture the relevant biological processes.

Various groups of organisms have different life cycles, including generation times and rates of response to environmental changes (e.g., speeds of migration). If we combine several groups of organisms that provide different life histories, we may be able to separate biological processes on several time-scales. The precondition is that our time control is good enough for recording these processes.

For example, the transition from the Late Glacial to the Holocene as one of the most rapid periods of warming was studied on the Swiss Plateau and in the western Alps at two sites with a record of oxygen isotopes (Gerzensee and Leysin) and three sites without carbonates (one of them presented here; Ammann, 2000; Ammann et al., 2000; Brooks, 2000; Schwander et al., 2000; Tobolski and Ammann, 2000; von Grafenstein et al., 2000; Wick, 2000).

The Responses of Flora, Fauna, and Vegetation to Rapid Climatic Changes

Figure 4 presents a comparison between the pollen and plant macrofossil records at the transition from the Late Glacial to the Holocene at three sites at different altitudes in the western Swiss Alps: Gerzensee at 603 m a.s.l., Leysin at 1230 m a.s.l., and Zeneggen at 1530 m a.s.l. At Gerzensee and Leysin, the oxygen isotopes of the bulk carbonates reflect the changes in the summer temperatures at this transition from the Younger Dryas to the Preboreal (independent from biostratigraphies). These isotope changes were correlated with the ones in the GRIP ice core, from which the timescale was then transferred (Schwander et al., 2000). At Zeneggen, however, no autochthonous carbonates occurred in the sediment, so the organic matter of the sediment (expressed as loss on ignition at 550 °C) was used as a proxy for productivity and thus indirectly for summer temperatures. During the cooling of the Younger Dryas, the lowest site remained forested (some opening of the forest is indicated by somewhat higher percentages of *Ephedra*, *Artemisia*, *Selaginella selaginoides*, and other heliophilous herbs, along with lower concentrations of macrofossils from trees). At the two sites at higher altitudes, forests were virtually absent and only a few trees survived during the Younger Dryas. Although Zeneggen is situated nearly 300 m higher, plant macrofossils from trees are richer than at Leysin. This may be explained by the special climate in the central Alps at Zeneggen/Valais, which has a very high insolation and high continentality. Zeneggen is only 30 km from Zermatt and 40 km from Gouillé Rion, where the modern timberline reaches a maximum elevation of 2400 m, with single *Pinus cembra* specimens currently up to 2500 m a.s.l. (i.e., 500–700 m higher than the timberline made by spruce on the northern slope of the Alps, including Leysin).

Placing the results of pollen and macrofossil analyses into a broader context, Figure 5 demonstrates the biotic responses of

groups of organisms other than plants. Changes in species composition and abundances (i.e., qualitative and quantitative changes) are summarized as the scores on the first axes of either PCA or CA (depending on the gradient length). At Zeneggen, the highest site (without a GRIP timescale), there seems to be the following sequence of responses: Cladocera first, pollen second, and plant macrofossils third. The rise in organic matter seems to last longer than the overall changes in the biota recorded in the PCA (axis 1). This is an indication that the changes in species composition in vegetation and cladoceran fauna as recorded in the PCA/CA lasted shorter than the increase in productivity as recorded in the LOI. At the two sites where the transition from the Late Glacial to the Holocene is recorded by oxygen isotopes, the biotic responses are quite complex. First, several changes had already occurred in the last third of the Younger Dryas, especially among the Cladocera. Second, several groups of organisms show two or three steps of overall changes. Some of these changes are associated with both the beginning and the end of the transition as recorded by oxygen isotopes (e.g., plant macrofossils at Gerzensee). Other biotic changes may then be controlled by succession, which was triggered by climatic change.

Conclusions on Biotic Responses

On the basis of not only pollen and plant macrofossils but also groups of aquatic invertebrates, the general conclusions about biotic responses to rapid climatic warming in southern central Europe from the Swiss study are the following (Ammann et al., 2000):

- (1) Biotic lags to the isotope record of temperature increase of organisms with various life cycles were less prominent than expected for both aquatic and terrestrial taxa. Responses occur within approximately 4–16 years, often within the sampling resolution.
- (2) The duration of the biotic response can last longer (or shorter) than the period of the climatic shift recorded in the isotopes. This depends on species-specific environmental thresholds and on biogeographical features such as range limits and the process of succession.
- (3) Altitudinal differences in sites are useful to capture fine-scale changes. Large climatic shifts such as the Younger Dryas are recorded at all altitudes but small-scale changes only at sensitive altitudes (i.e., near the ecotones of the taxa present).
- (4) The nature of the biotic response to climatic change involves at least four groups of processes acting on different timescales:
 - i. Biogeographical changes include local (or global) extinction as well as immigration. Species migration is the slowest of the three processes; migration velocity depends, among other things, on generation times and the maximum distances of dispersal jumps. Migration (i.e., the shift of range limits) may occur in less than 1 year (e.g., algae, microorganisms, and some insects) or it may take millennia (e.g., trees). Species migration also depends on the distances involved and on barriers (e.g., mountains or oceans).
 - ii. Population dynamics after arrival of a species in an area involve the building up of populations. The time needed for this depends, among other things, on age

Figure 4 Altitudinal transect of pollen (curves) and plant macrofossils (histograms) as stratigraphies covering the transition from the Younger Dryas to the early Holocene (preboreal); Gerzensee and Leysin presented on a GRIP timescale. At Gerzensee, the forest did not disappear during the Younger Dryas but was more open than before and after. At Leysin and Zeneggen, only a few trees survived the cool period of the Younger Dryas. Timescale after Schwander et al. (2000), and botanical results combined from Wick (2000) and Tobolski and Ammann (2000).

Figure 5 Biotic responses to the rapid warming at the end of the Younger Dryas in the same sites as in [Figure 4](#). The qualitative and quantitative changes in species composition and abundances are summarized as scores of the first axis on a PCA of one or two groups of invertebrates and as a CA for plant macrofossils. Cladocera seem to respond first; pollen, plant macrofossils, and chironomids respond in complex ways and usually in two steps. Responses often occur within the sampling resolution. Modified from Ammann B, Birks HJB, Brooks SJ, et al. (2000) Quantification of biotic responses to rapid climatic changes around the Younger Dryas—A synthesis. *Palaeogeography Palaeoclimatology, Palaeoecology* 159: 313–347.

of first reproduction and generation time. Population changes occur at an intermediate rate.

- iii. Productivity (e.g., pollen production per year or tree ring width): This is the fastest type of response and can occur within 1 year.
- iv. Genetic variability within populations may lead to adaptation. Processes of population genetics (including phenomena such as bottle necks, founder effects, and drift) occur on all timescales and are related to the groups of processes mentioned under (i) and (ii). Both, paleo-records (e.g., for spruce [Latalowa and van der Knaap, 2006](#)) and phylogeography (e.g., for spruce [Scotti et al., 2000](#); [Sperisen et al., 2001](#)) provide

complementary information on tree migration (as an integrated example see for beech [Magri et al., 2006](#)). Again, the results of plant macrofossils may be important here for the taxonomic and spatial distinctions (i.e., the distinction between tree species within a genus and the distinction between presence and absence in the past). An important bridge between paleoecology and phylogeography may develop if the analysis of ancient DNA becomes less problematic, provided that DNA degradation is not too serious. In this context, the analysis of plant macrofossils will become even more important by providing species-specific samples.

Pollen Analysis, Principles

H Seppä, University of Helsinki, Helsinki, Finland

Introduction

Pollen analysis, the study of fossil pollen and spores, is the principal technique for long-term (10^2 – 10^5 years) vegetation reconstructions. Pollen-stratigraphic results have greatly shaped the development of ideas regarding the nature of vegetation and climate during the Quaternary glacial–interglacial cycles. They have provided unique insights into long-term ecological patterns and processes such as the dispersal dynamics and distribution changes of tree species; the ancestry, development, and continuity of modern plant communities and biomes; and the sensitivity and response mechanisms of plants and vegetation to climate changes. They have also shed light on the origin and spread of early agriculture and the role of humans in influencing vegetation.

Many flowering plants liberate enormous quantities of pollen into the air, the production of pollen grains in one forest hectare can be billions (Pohl, 1937). In the atmosphere, pollen is efficiently transported and mixed by wind. Pollen is therefore widely and evenly spread, and fossil pollen records are available from various sedimentary environments such as seas, lakes, ponds, peatlands, soils, and humus layers. The pollen concentration of sediments is usually high; in lake sediment, pollen concentration may often reach 10^3 – 10^5 grains cm^{-3} (Allison et al., 1986), and pollen analysis can often be carried out on sediment samples smaller than 1.0 cm^3 in volume. Where sediment deposition is continuous, sedimentary pollen records may provide an unbroken sequence of useful data. This is one of the major advantages of pollen analysis, namely, a methodological flexibility permitting adjustment of the technique according to the time dimensions relevant for the study. Consequently, the applications of pollen analysis can vary from investigations of the vegetation dynamics of the continents during the glacial–interglacial cycles to studies of annual to subdecadal patterns of the secondary plant succession after a local forest disturbance.

The spread of airborne pollen by wind also results in methodological complexities, some of which constitute the most important limitations and pitfalls of the method. The crux of the problem is that many different patterns of plant abundance can yield the same flux densities of pollen types (Prentice, 1988). The reason for this is that the pattern of pollen dispersal from a singular source, such as a single tree, is typically

leptokurtic: most of the pollen is deposited within 10^1 – 10^3 m from the source, but a small proportion of pollen is transported in the atmosphere over longer, theoretically indefinite, distances (Hjelmroos and Franzén, 1994). It is therefore difficult for a paleoecologist to know whether small proportions of a given taxon in sediment reflect a few individuals of the plant species that formerly grew in the vicinity of the coring site, or whether they came from a larger population that grew far away from the site (Davis, 2000). The problem of precisely defining the pollen source area and quantitatively reconstructing past plant assemblages is crucial, not only because of the risk of erroneous interpretations of the nature of past vegetation and environments, but also because it has been an obstacle for utilizing the full potential of pollen analysis as a central, routinely used tool in ecological research.

This article reviews the general features of pollen analysis as a method in Quaternary science. The focus is particularly on the theoretical basis of pollen analysis as a technique for vegetation reconstruction. Some examples of the application of the technique are also included. These are selected to reflect the variable time and space scales that characterize the use of pollen analysis and also to highlight the problems and pitfalls that limit the use of the technique.

Origin of Pollen and Spores

Pollen grains are unicellular, microscopic (mostly between 15 and $100 \mu\text{m}$) organs that contain the male gametophyte generation of plants. Spores are, in principal, the corresponding organs of the pteridophytes (ferns, mosses, and allies) but differ morphologically and functionally from pollen (Figure 1). In practical terms, pollen analysis usually comprises the identification and tallying of both pollen and spores in an assemblage. Spores are mostly similar in size to pollen grains and have similar preservational characteristics. Hence, any sample that contains pollen is likely to yield spores as well. Pollen grains are produced in the anthers of the male flowers of plants and released during flowering. The purpose of the pollen grain is to germinate on a stigma and provide the sperm nucleus to the ovule. For this purpose, pollen is carried by wind, water, insects, or other animals from the anthers to the stamen of the female flower. Wind-pollinated plants, such as most of the conifers, many other

Figure 1 Some examples of different kinds of pollen and spore types: (a) *Vaccinium vitis-idaea* (crowberry), a tetrad pollen type; (b) *Potamogeton natans* (broad-leaved pondweed), an inaperturate pollen grain; (c) *Tussilago farfara* (coltsfoot), an echinate trizonocolporate pollen type; (d) *Cystopteris fragilis* (fragile fern), a monolete spore; (e) *Corylus avellana* (hazel), a trizonoporate pollen type; (f) *Silene dioica* (red campion), a polyaperturate pollen grain. Images from Uppsala University Paleobiology Website: <http://www.palaeontology.geo.uu.se>.

angiosperm trees, grasses, and sedges, usually produce more pollen than animal-pollinated plants. The estimated annual pollen production rates of common wind-pollinated plants reflect the enormous amounts of pollen production. One shoot of hemp can produce over 500 million pollen grains, and a shoot of lodgepole pine (*Pinus contorta*) can produce 8–9 million pollen grains per year; a male plant of common sorrel (*Rumex acetosa*) produces 400 million pollen grains; one 10-year-old branch system of birch, spruce, or oak can produce more than 100 million grains, and pine, over 350 million pollen grains in a year (Pohl, 1937). The pollen productivity of the animal-pollinated plants is, in general, much less, but the production rates of some animal-pollinated plants, such as lime, willow, and heather, are comparable to those of wind-pollinated plants.

Sedimentation and Preservation

Only a fraction of the produced pollen grains falls on the stamen of the maternal part of the flower and fertilizes the ovule. A great majority of pollen falls on land or water and decays, unless pollen is deposited in an anoxic sedimentary environment where it will be preserved. During sedimentation, the cytoplasm (cell contents) of pollen grains is lost, and the fossil pollen grains consist of the hard and chemically resistant outer layers or exines. In addition to the sedimentary environment, preservation of pollen grains depends on the thickness and sporopollenin content of the exine, so some pollen grains preserve better in sediments than others.

Various types of corers and samplers are used to recover sediments from different sedimentary contexts, such as lakes and peatlands (Glew et al., 2001). Pollen is extracted from

sediments in the laboratory. Sediment subsamples are processed in the laboratory by a series of physical and chemical treatments. The standard procedure includes treatment of the sample with dilute hydrochloric acid, potassium hydroxide solution, hydrofluoric acid, and a mixture of sulfuric acid and acetic anhydride (Bennett and Willis, 2003; Fægri and Iversen, 1991; Moore et al., 1991). Hydrofluoric acid is a strong acid that dissolves the silicates; sulfuric acid and acetic anhydride form a chemical compound for acetolysis that removes cellulose and most of the other organic remains from the subsample. The grains may be stained with safranin, which can help make them more distinctive under the microscope. The grains are then suspended, usually in silicone oil or glycerine jelly. Pollen grains are normally counted with 500× magnification.

Plant–Pollen Representation

The results of the pollen counts are usually presented in pollen diagrams showing the percentage values of all or selected pollen types. It is important to note that most pollen grains cannot be identified to the species level. Most are identified either to the genus or family level only. Palynologists working in a given region may come to recognize two or more types of pollen within a genus or family that are specific to that region and can identify these on the basis of identification keys. Pollen of all grass species are identified at the family level (Poaceae), pollen of different pine species at the generic level (*Pinus*), and the three common North-European birch species cannot be distinguished from each other.

Since the first comparisons of pollen diagrams and modern plant abundances, it has been known that pollen records do

not directly reflect plant abundances because some taxa are overrepresented and others underrepresented in pollen samples. A potential way to transform the fossil pollen percentage values to correspond more precisely with real relative plant abundances is to use various types of statistical correction factors developed individually for each pollen type. In order to obtain such factors, it is necessary to study the pollen–plant relationships by comparing modern plant abundances and modern pollen values within forests. Foundations for this work were laid in the temperate woodlands in North America and Europe in the 1960s. Davis (1963) defined an index, termed the *R*-value, for describing the ratio between pollen and vegetation percentages and used the *R*-value to convert the original pollen sums to reflect the vegetation percentages. In contrast, Andersen (1970) compared absolute pollen accumulation values analyzed from moss polsters with the vegetation percentages of corresponding tree species in the same woodland. Significantly, he showed that models describing pollen input cannot consist only of multiplying terms that reflect the relative productivity differences but must also include additive terms to account for the background pollen component originating outside the vegetation area used for calibration purposes. The relationship between pollen percentage values and the vegetation percentage can therefore be depicted as a linear regression curve in which the slope indicates the pollen productivity of the given species and the *y*-axis intercept shows the amount of background component of the same species transported from outside the study area.

An improvement combining features of both the *R*-value method and Andersen's linear regression method is an extended *R*-value (ERV) method, which is based on the percentage values but takes into account the background pollen input (Prentice, 1988; Prentice and Parsons, 1981). In addition, the ERV method includes a site factor that ensures that the corrected percentages at each site total 100%. The ERV model presents the relationship between the pollen percentage and the surrounding vegetation as:

$$p_{ik} = \alpha_i v_{ik} f_k + z_i$$

where p_{ik} is the pollen percentage of the taxon *i* at site *k* and v_{ik} is the abundance of the taxon in the vegetation. α is a coefficient describing the pollen production of taxon *i*, and z_i is the background component of pollen coming from outside the study area. f_k is the site factor ensuring that the right-hand side of the equation will total 100%. It is important to note that these taxa have to be identified at the same taxonomic level. Thus, if the pollen taxon is *Pinus*, then the vegetation taxon must also be *Pinus* (genus level) and would include all the pine species in the area, subsumed at that taxonomic level. There is often confusion on this point, whereby people talk about *Pinus* (pollen taxon, genus level) and then start discussing pine species individually.

The site factor can be expressed as:

$$f_k = \left(1 / \sum_j \alpha_j v_{jk} \right) \left(1 - \sum_j x_j \right)$$

Due to the inclusion of the site factor, ERVs also account for the Fagerlind effect (Prentice and Parsons, 1981), a non-linearity typical of pollen percentage data. The linear regression methods assume a linear relationship between the pollen

values and plant abundance. However, the percentage pollen data are not linear, because they must total 100%. Therefore, an increase in the pollen type of one taxon must be accompanied by a decrease of another, even if the actual abundances of the other taxa remain constant. In general, the ERVs give a markedly better fit to pollen percentage–plant abundance data than do the classical linear regression models.

Although valuable and rational in principle, the generation of reliable correction factors is a complicated process, and their use is never simple or straightforward. Nevertheless, when the representation differences between the main plant taxa are significant, the corrected values undoubtedly often reflect the original plant abundances more closely than the uncorrected values. Yet, it is important to remember that the linear models for pollen input assume constant background pollen and constant pollen productivity for any given taxon, whenever it appears, implying that the use of correction factors is constrained in space and time to the overall vegetation type for which they were originally generated. Vegetation changes during the Holocene have been of such magnitude that the background pollen input has undoubtedly changed, and the linear relationship obtained from modern samples is therefore not a reliable estimate for correcting the fossil pollen values on millennial or longer timescales.

Pollen Dispersal and Model-Based Correction Approaches

To fully account for the complexities of the dispersal of pollen in the atmosphere, a more comprehensive model linking the regional and local vegetation patterns and defining the source area of pollen is needed. Intuitively, it is obvious that small hollows (small openings within forests) receive great quantities of pollen from the vegetation around the sampling site, whereas centers of larger basins, for example, lakes, receive predominantly wind-transported and well-mixed pollen from the air. Consequently, the source area of pollen records from lakes is the regional vegetation, whereas small hollows have a smaller source area and reflect more the local vegetation around the site (Jacobson and Bradshaw, 1981). This simple model has been used as a general rule of interpretation of pollen-stratigraphic records from sampling sites of different sizes. Studies designed to investigate stand-scale forest disturbance or local prehistoric land use can use small hollows or lakes with a radius of less than 50 m, whereas palynologists interested in regional-scale pollen signals (e.g., in climate reconstructions) need to focus on larger lakes, for example, with a radius of 250 m or more. Such a qualitative and intuitive definition does not, however, permit specification of the spatial scale of the study with the precision that would be comparable to that of modern ecological studies. A challenge for palynologists has been to define the pollen source areas more quantitatively and precisely, and, hence, to generate more spatially precise vegetation reconstructions (Figure 2 and Table 1).

Comprehensive efforts to model pollen dispersal and define the source areas have been carried out since the 1980s, and the resulting model is usually termed the 'Prentice–Sugita model' after its key developers (Prentice, 1988; Sugita, 1994).

Figure 2 The influence of the sample size on the pollen assemblages obtained from lakes of different radii in a simulated patchy landscape. (a) An example of the simulated landscape, with forest stands in a matrix of grass-dominated vegetation. See Table 1 for stand compositions. (b) Simulated pollen assemblages among 30 lakes with different sizes. The percentage values stabilize when the lake size is 48 ha or larger, indicating that the lakes of this size sense the vegetation as homogenous in this particular landscape at the significance level $\alpha = 0.05$, using the likelihood ratio statistics G^2 . Source: Sugita S (2007a) Theory of quantitative reconstruction of vegetation I: Pollen from large sites REVEALS regional vegetation composition. *The Holocene* 17: 229–241.

The principal purpose of the model is to quantify the pollen input from the vegetation surrounding the sampling site, either to the center of a basin or on the entire surface of a basin. It is important to assess the pollen inputs to the center of a basin

because this is the place from which sediment cores are very often taken for pollen analysis purposes. According to the model, the input depends on the pollen productivity of the plant species contributing to the pollen rain at the site,

Table 1 Stand characteristics in the simulation experiment in Figure 2. The landscape has four stand types. The distribution of taxa in each stand is assumed to be homogeneous. Taxa	Matrix	Patch type 1	Patch type 2	Patch type 3	Overall composition
Proportion in area	0.40	0.30	0.20	0.10	
Mean size $\pm$ SD (ha)		30 $\pm$ 10	15 $\pm$ 5	2 $\pm$ 1	
Poaceae	0.95	0.01	0.05	0.30	0.423
<i>Picea</i>	0.01	0.75	0.01	0.01	0.232
<i>Betula</i>	0.01	0.20	0.25	0.30	0.144
<i>Quercus</i>	0.01	0.03	0.14	0.38	0.079
<i>Fagus</i>	0.02	0.01	0.55	0.01	0.122

the mean plant abundance at a given distance from the center of the basin, and a pollen deposition function. The pollen deposition function, based on Sutton's physical equation for a ground source (Prentice, 1988), defines the proportion of pollen remaining airborne at a given distance from the plants and is individual to all pollen types because of their individual settling velocities. A characteristic feature common to the shapes of all the deposition functions is their leptokurtic nature: a majority of pollen will be deposited near the source, but a proportion will be transported over theoretically indefinite distances (Prentice, 1988). The distributions may also be highly skewed, due to prevailing wind directions or terrain. This pattern of pollen dispersal from a source explains why plants near a lake are more strongly represented in the pollen input of a basin than those growing progressively further from the basin and implies that some form of distance weighting must be applied to plant abundances while modeling or comparing modern pollen assemblages with modern plant abundances (Prentice, 1988; Sugita, 1994).

A more comprehensive theoretical modeling approach to understand and correct for the differences in pollen productivity, pollen dispersal, and sampling size is called the Landscape Reconstruction Algorithm (LRA; Sugita, 2007a,b). LRA consists of two models. Regional Estimates of VEgetation Abundance from Large Sites (REVEALS) is a model to reconstruct quantitatively the regional composition of vegetation through time. The REVEALS model defines the pollen loading, the average input of pollen on area unit, in the center of a large lake on the basis of mean plant abundance of a given taxon, pollen productivity of each taxon, radius of the lake, maximum distance of the plant from the lake, and a dispersal function. Once the pollen loading is known, it is possible to use the basic equation of the REVEALS model to estimate the past mean plant abundances and hence to reconstruct the past regional composition of vegetation. Simulation experiments and empirical tests have shown that the lakes of size ≥ 100 –500 ha are generally large enough so that the pollen data can provide accurate estimates of regional vegetation (e.g., Hellman et al., 2008).

Once the regional vegetation change through time has been reconstructed with the REVEALS model, it is possible to use the LRA to reconstruct local vegetation features from small sites. This requires the incorporation of the Local Vegetation Estimates (LOVE) model to quantify and subtract background pollen to produce quantitative vegetation reconstructions

within the relevant source area of smaller sites (Sugita, 2007a). The central concept here is the 'relevant source area of pollen' (RSAP). RSAP refers to the size of the area around a given study site, which controls the individualistic features in the pollen assemblages of the site in relation to the uniform regional background pollen. The vegetation patterns within the RSAPs are therefore reflected in the lake-to-lake differences in pollen input in areas of the same regional vegetation (Davis, 2000; Sugita, 1994). The RSAP for a site can be estimated by calculating the r^2 , or maximum likelihood function score, as a measure of goodness-of-fit between the pollen assemblage and the distance-weighted plant abundance around each study site (Sugita, 2007b). The distance beyond which r^2 , or the likelihood score, no longer improves defines the radius of the RSAP for that particular site.

LOVE is theoretically similar to the inverse form of the ERV, but the important difference is that, unlike the ERV, LOVE does not assume a constant background pollen but incorporates it as a parameter that can vary through time and can be estimated using the REVEALS model. Thus, the ideal LRA approach to estimate past vegetation composition in given specifically defined areas in a patchy landscape is to combine the pollen records from a large lake and the REVEALS model to reconstruct past regional vegetation and to combine the pollen records from a number of smaller sites and the LOVE model to reconstruct the past vegetation within the RSAPs of the smaller sites, corresponding with the study areas of interest, for each time window. This provides vegetation reconstructions at both local and regional scales (Figure 3).

A key requirement for the use of the LRA is the existence of pollen productivity and pollen dispersal estimates, reflected by pollen settling velocities, at least for the most common and important plant taxa, especially in northwest Europe where it has been studied most intensively. Obtaining these estimates is a non-trivial task, but the tests have shown that once the information is available, REVEALS and LOVE models have the potential to produce more accurate, quantitative vegetation reconstructions. As with all models, the LRA procedure contains many assumptions regarding pollen transportation and deposition mechanisms, local and regional vegetation patterns, and basin configuration (Sugita, 2007b). It does not, for example, account for stream-borne pollen, a major source of pollen in many lakes. It is thus unclear how reliably the approach can be applied to produce corrected vegetation

Figure 3 (a) A lake of about 20 ha, a typical sampling site for pollen analysis focusing on reconstruction of postglacial regional vegetation patterns in the boreal zone of Europe. The dominant trees in the surrounding forest are species of pine and spruce (Photo: Charlotte Sweeney). (b) Small forest hollow in Suserup Skov, Denmark. Photograph by Gina Hannon.

reconstructions, particularly outside the lake-rich landscapes of the temperate and boreal biomes.

A potential way to avoid the problems related to percentage data and to estimate plant abundance in the surrounding landscape independently for each species is to calculate the direct pollen accumulation rate (PAR) values individually for each taxon (keeping in mind the caveat that this does not equal plant species in most cases). Instead of relative percentage data, PAR is a calculation of the accumulation of pollen at the sediment surface (per cm^2 or other space unit) per year (Davis and Deevey, 1964). This value is individual and independent for each pollen and spore type and therefore avoids the problems arising from the interdependent nature of the relative records. PAR values are usually calculated for the most important tree species, the aim being for PAR values to provide precise records of past tree population sizes, measured either as canopy coverage or biomass. However, methodological investigations have shown that the PARs can vary by factors from 3 up to 10, not only within lakes, but also between lakes located in the same area and surrounded by similar vegetation. The predominant reason for the within-basin variability of PAR is the spatially and temporally uneven pattern of matrix sedimentation and pollen deposition in the lake basin (Seppä et al., 2009b).

Despite these caveats, in some regions, the PAR technique has been successfully applied to estimate past tree population density changes around the study lakes, because they can help to circumvent the problems arising from the nonlinearity of pollen percentage data. Especially valuable have been the applications of PAR values to investigate past competitive interactions, for example, the population growth of an invading tree taxa and the associated population declines of other, less competitive taxa (Figure 4; Bennett and Lamb, 1988; Seppä et al., 2009a). PAR values can be also valuable in the ecotones of the forested and treeless biomes, such as boreal forest and the arctic tundra, where the advances or retreats of the main tree taxa are recorded as major changes in PAR values, while less change is apparent in percentage values. In suitable circumstances, it is possible to use modern surface samples or pollen trap results for generating

threshold PAR values that define the absence, presence, or dominance of key tree species and apply these values to the fossil PAR records for providing semiquantitative estimates of past population densities in the study region. To go further in the direction of quantification will require a survey of modern population sizes of key tree species in the RSAPs of modern sites used for calibration of the PAR values (Figure 5; Seppä et al., 2009b).

Applications of Pollen Analysis

Local-Scale Studies

As indicated by the pollen representation models, the RSAPs for pollen records obtained from small forest hollows or moss polsters are about 50–200 m. Such records reflect forest history on a stand scale, the same spatial scale on which most modern forest ecologists operate, and the scale for which the classical forest succession models describing the predictable sequence of plant communities on annual to decadal time-scales were developed. Consequently, paleoecologists working on local-scale pollen studies can share the concepts, research problems, techniques, and perspectives of forest ecology. This provides opportunities for close collaboration with modern ecologists, whose understanding of local dispersal, establishment, and other time-related ecological processes emerges from observations of contemporary processes and may thus underestimate the underlying critical historical factors (Bradshaw, 1988).

Another major advantage of focusing on local-scale studies is that it is often possible to relate reliably past changes in species composition and structure to external factors causing the changes. Independent evidence for the external factors can be obtained, for example, from analyses of sediment charcoal, tree rings, historical archives, and climate reconstructions based on techniques independent of vegetation dynamics. Comparisons of these records with local-scale pollen records often demonstrate the importance of such local processes as fire, human disturbance, and storms in vegetation dynamics. Immigration or expansion of a species that is simultaneous with a local disturbance

Figure 4 Scatter diagrams showing the relationship between pine (*Pinus*) and maple (*Acer*) pollen percentages and their basal area (BA) percentages in the surrounding vegetation. Pollen percentages for individual sites are constant, but three different vegetation sampling areas have been surveyed: 20 m = 20-m vegetation sampling radius, 70 m = 70-m vegetation sampling radius, and 120 = 120-m vegetation sampling radius. Results from two different data sets are shown, from Fish Creek (open circles) and the eastern Adirondacks (closed circles) in northern New York, USA. Scatter plots such as these provide the basis for estimating the pollen productivity of plant taxa; taxa with high productivity have a steep slope, and those with efficient dispersal have a high y-axis intercept. Source: Jackson ST and Kearsley JB (1998) Quantitative representation of local forest composition in forest-floor pollen assemblages. *Journal of Ecology* 86: 474–490.

such as a fire may have taken place as a response to the altered growth conditions and interspecific competition. For example, the local establishment of beech at its distribution limit in northern Europe seems to have been greatly facilitated by human activities, especially disturbance by fire, and this association with historical disturbances is reflected in the species' modern patchy distribution pattern (Figure 6; Bradshaw and Lindbladh, 2005). On the other hand, stand-scale invasions during intervals with no evidence for disturbance, such as that of hemlock in its western range limit in North America, may be related to rapid or gradual climate changes and associated changes in local growing conditions (Figure 7; Parshall, 2002). These examples reflect the individualistic response patterns and invasion histories of tree species and demonstrate the great relevance of local-scale, pollen-analytical investigations for basic and applied forest ecology.

Regional-Scale Studies

Conventionally, pollen records have been produced from small- to medium-sized (roughly 10–50 ha) lakes and mires and reflect the vegetation of the surrounding few hundreds of square kilometers. Pollen records on this scale have had a major influence on our understanding of vegetation history and concepts of population, community, and biome dynamics during the Quaternary Period. Regional-scale pollen records have shown dramatic vegetation changes during glacial–interglacial cycles in regions adjacent to ice sheets and have provided unique insights into the nature of vegetation during the previous interglacials. They have also shed light on significant vegetation zone shifts during the interglacials, such as the early- to mid-Holocene expansion of savannah vegetation into the modern Saharan desert in Africa, the northward advance of the boreal conifer forest zone of the Northern Hemisphere, and the major deforestations caused by humans in many ecosystems during the late Holocene.

By synthesizing data from regional records over large areas, it has been possible in some instances to reconstruct the location of refugia of the main tree species during the last glaciation, and pollen data have helped map their subsequent spread during the interglacial (Bennett, 1997; Huntley and Birks, 1983). According to conventional interpretation, a post-glacial immigration of a new plant species into a region is reflected in a distinct rise of the percentage values of the corresponding pollen type. Many recent studies, however, have challenged this view by showing that the regional-scale pollen records may regularly provide underestimates for the date of immigration of the new species into a given area. The occurrence of macrofossils and stomata of tree species have provided firm evidence for the presence of tree species hundreds or thousands of years before any significant rise in the taxon's pollen curve (Välranta et al., 2011). This suggests that species may have occurred sparsely, probably under conditions limiting both population growth and pollen productivity, until a population expansion occurred in response to a change of external factors. In many cases, it may be this expansion that is reflected in the visible rise of the pollen curve, not the immigration. Motivated by these observations, some palynologists have also adopted a fresh approach to interpreting

Figure 5 Pollen accumulation rate (PAR) values provide a means of estimating past plant abundances independent of pollen percentage values. Here, the PAR records of Norway spruce (*Picea abies*) and small-leaved lime (*Tilia cordata*) are presented from two lakes in Fennoscandia. The black arrow represents the time of the immigration of spruce, and increasing PAR values show its rise to dominance. The concurrent decline of lime PAR values indicate that the spruce population expansion happened at the expense of the lime population, mostly as a consequence of the competitive replacement. Source: [Seppä H, Alenius T, Giesecke T, Bradshaw RHW, Heikkilä M, and Muukkonen P \(2009b\)](#) Invasion of Norway spruce (*Picea abies*) and the rise of the boreal ecosystem in Fennoscandia. *Journal of Ecology* 97: 629–640.

pollen data. A comparative examination of combined and mapped pollen records from Beringia, a region that had been earlier interpreted as being tundra with no forests or even trees present, showed consistent patterns indicating a presence of tree species during the Last Glacial Maximum and subsequent expansions of the populations ([Brubaker et al., 2004](#)). Overall, the detection of a presence of taxon from pollen data, especially in a sparsely vegetated region, remains difficult, and the most reliable results can be achieved by an integration of pollen analysis with analyses of stomatal and plant macrofossil evidence from the study region ([Birks and Birks, 2001](#)).

Continental-Scale Reconstructions

The continental-scale applications of pollen analysis usually involve pollen-stratigraphic analyses of long sediment cores obtained from ocean bottoms ([Margari et al., 2010](#); [Sanchez-Goni et al., 2008](#)) or from continental sites where sediment has

accumulated undisturbed over tens of thousands of years, for example, in crater lakes or lakes located in tectonic depressions beyond regional glacial ice limits ([Lozhkin et al., 2007](#); [Tzedakis et al., 2006](#)). These sediment cores span tens or even hundreds of thousands of years and can cover full glacial–interglacial cycles. In addition to providing evidence of the nature of vegetation during the previous interglacials and interstadials, the records reflect the pace of vegetation dynamics in response to the Milankovitch-scale climate dynamics, demonstrating alternations of forests and treeless vegetation types consistent with variations in solar insolation and global ice volume. The long records obtained from terrestrial sites in particular allow integration of the land-based and marine records (e.g., the marine isotope and other records) and hence a synthesis and correlation of marine and terrestrial ecosystems.

A difficulty with long pollen records is that their chronological control is, in general, weakly constrained, often being obtained by correlating distinct events and intervals of the pollen diagrams with precisely dated, long records such as ice cores.

Figure 6 Stand-scale pollen records reflect the contrasting invasion patterns of Norway spruce (*Picea abies*) and European beech (*Fagus sylvatica*) in northern Europe. (a) Pollen percentage values (mean + SD) with a total terrestrial pollen sum for Norway spruce and European beech in small hollow samples with and without cereal grain pollen. The percentages of beech are higher when cereal pollen is recorded in the same samples, while spruce does not indicate similar relationship. (b) The mean forest stand composition in southern Scandinavia during the invasion of spruce and beech. The percentage values (mean + SD) were adjusted by stand-scale correction factors that allow for differential pollen representation. The light brown bars indicate sites invaded by Norway spruce and the brownish green bars sites invaded by European beech. Norway spruce favored forest stands where birch, pine, or beech was abundant, whereas European beech was established in sites with oak, alder, hazel, and other deciduous trees. All sites are totally or mostly 'closed canopy' sites with RSAP roughly comprising the surrounding 20–50 m. Source: Bradshaw RHW and Lindbladh M (2005) Regional spread and stand-scale establishment of *Fagus sylvatica* and *Picea abies* in Scandinavia. *Ecology* 86: 1679–1686.

More reliable correlations can be obtained by analyzing continental and marine proxies from the same deep-sea sequences or by applying tephrochronological techniques to generate more precise chronologies for the continental cores (Figure 8). Improved chronological precision has prompted palynologists to investigate the timing and duration of the interglacials in pollen records and to examine whether the recently realized abrupt climatic events and cycles typical of the glacial intervals influenced the vegetation of the continents adjacent to the Atlantic. Long continental pollen records can also be used for quantitative climate reconstructions because, on the timescale

represented by these records, vegetation patterns were predominantly controlled by the climate regimes. Possibilities for precise reconstructions are limited by the often low level of analog between modern pollen assemblages and those representing the glacial intervals. In general, however, the results indicate trends that are comparable to those obtained by independent techniques such as the stable isotope records of ice cores.

Conclusions and Future Directions

Historically, the main function of pollen analysis in Quaternary-stratigraphic investigations has been to identify chronostratigraphic periods, to correlate sediment sequences, and to provide general reconstructions of vegetation and climate. Conventional pollen diagrams are still valuable when produced in new regions or collected from key sites where long, uninterrupted pollen records can be obtained, but in regions where the palynological studies have a long history, for example, in eastern North America and Europe, conventional pollen analysis is increasingly being replaced by carefully designed studies that address specific questions and concentrate on specific time intervals. This is particularly so in the application of pollen analysis in Quaternary paleoclimatology, where the recent discoveries of major Quaternary climate changes, such as Heinrich events during the last glacial, the abrupt warmings and coolings during the last glacial termination, and the short-lived cold interval about 8.2 ka ago, highlight the need to focus on high-resolution pollen-stratigraphic data from optimally located sites in order to investigate the occurrence of these climate events in the continental regions. A related emerging application of pollen analysis is its use as a method in Earth system science, for example, to reconstruct past continental-scale land cover changes and assess their importance in the global carbon cycle and the climate system (Gaillard et al., 2010).

There is another major trend in pollen analysis, where the aim is to reconstruct past vegetation in more precise terms. The fundamental objective is to provide quantitative vegetation reconstructions that incorporate central ecological attributes such as floristic composition, species abundance, and the spatial distribution of plants in an explicitly defined context of time and space and assess the role of internal and external factors as drivers of change. For this purpose, we must to improve our understanding of modern relationships between vegetation patterns and pollen input, including the critical processes of pollen productivity and dispersal from plants to the deposition site. We must also improve our ability to identify pollen to lower taxonomic resolution (i.e., to the species level), so that plant records and pollen records can be more directly compared. Pollen analysis will have only limited utility (and not reach its full potential) as long as we are able to identify the majority of types to just genus level. Formidable (and perhaps intractable) taxonomic and identification issues remain.

Despite having made significant progress, pollen analysts are still far from reaching these ambitious goals but remain motivated by the breakthrough potential of the method in truly quantitative vegetation reconstructions.

Figure 7 A combined use of stand-scale and regional-scale records can provide a detailed picture of past population dynamics, as exemplified by the investigation of hemlock population history in Wisconsin, USA. Hemlock pollen percentage values from a lake ((a) Hemlock Lake) show the regional arrival of Canadian hemlock (*Tsuga canadensis*) at about 2000 cal years BP. Four stand-scale records (b–e) from small hollows indicate that after its spread, hemlock occurred in the region as scattered populations until a rapid expansion at about 500 cal years BP. The expansion has been a regionally synchronous event, suggesting a climatic change toward moister and cooler conditions. Records of stomata (st) analyzed from the pollen samples corroborate the pollen evidence. Introduction

Climate strongly influences the geographical distribution of plants and of vegetation types because not all plants have evolved the same tolerances for extreme temperatures and the same temperature and moisture requirements for optimal photosynthesis (Woodward, 1987). Past variations of the climate will therefore have influenced the distribution of terrestrial vegetation, and the changes in these distributions may be reconstructed by studying the record of fossil pollen recorded in lake sediments and peat bogs (see [Pollen Analysis, Principles](#)). However, the relation between the pollen composition of lake sediments (pollen diversity and relative abundance) and the species composition of the surrounding vegetation is not straightforward because pollen production, dispersion, and preservation vary from one species to the other. In order to reconstruct past climates from pollen data, it is therefore necessary to directly relate modern pollen data to climatic values, and then apply this relation to fossil pollen samples.

The increasing concern over the current and future changes in climate has led to greater interest in the use of pollen studies to quantify past climate changes, notably for intervals of large variations in climate such as the transition between glacial and interglacial intervals. The results obtained by the transformation of pollen data into climate equally form an ideal source of data for testing the output of global circulation models during the past (paleo-GCMs), a process that allows an assessment of these models for future predictions under different conditions (see [Data–Model Comparisons](#)).

Past variations of the climate have influenced the distribution of terrestrial vegetation, and the changes in these distributions

may be reconstructed by studying the record of fossil pollen recorded in lake sediments and peat bogs (see [Pollen Analysis, Principles](#)). The underlying principle of all attempts to reconstruct climate from pollen data is that of uniformitarianism, that is, the information required for understanding past conditions may be obtained from the relationship between the modern distribution of the taxa concerned and the climate (Birks and Birks, 1980). The distribution of each taxon is controlled by a set of climatic limits, and combinations of taxa indicate a particular set of conditions, with greater or lesser accuracy. By relating the modern distribution of taxa and climate, and subsequently applying this relationship to the observed assemblage of fossil pollen taxa, it is then possible to reconstruct the climate that shaped past plant communities, by using the presence/absence or the relative abundance of the various pollen taxa identified ([Figure 1](#)).

Theoretically, pollen-based climate reconstructions are derived from an inversion of functions that describe the way in which biological organisms respond to their environment. In practice, non-causal statistical equations linking climate and modern proxy data are calculated and then applied to fossil assemblages to reconstruct past climates.

In any form of climate reconstruction based on a transfer function, it is assumed that (1) modern pollen assemblages relate to their present-day environment, (2) the climatic parameter to be reconstructed is either a controlling factor on the abundance of the taxa or is linearly related to another controlling factor, (3) the ecological responses of the taxa have not changed with time, (4) variations in the modern data set are unaffected, or only negligibly, by environmental factors other than the one to be reconstructed (Birks, 1995).

Figure 1 Summary diagram illustrating the steps necessary for the construction of a transfer function. (Modified from an unpublished diagram by S. Juggins.) Modern samples are taken from environments corresponding to those of the fossil samples. A transfer function is formed between the modern samples and the corresponding modern climatic parameter. The transfer function is then applied to the series of fossil samples, to provide an estimation of paleoclimatic changes.

The most intuitive approach is to compare the present-day distributions of selected species with the corresponding distribution of climate variables thought to be critical in determining the distributions of each species. This approach, called indicator species, is univariate because the species are analyzed separately and with respect to one climatic variable at a given time. However, this approach is somewhat limited, because in reality species respond to combinations of climatic variables and are limited by different climatic factors in different parts of their ranges. Different climatic factors are intercorrelated and these correlations are a function of the climatic regimes in which the species live. The relationship of a species to climate may change within its ecological range due to differentiation of physiological ecotypes. The climatic influence on species is made more complex by the competitive effects of other species present.

Multivariate indicator species approaches are preferable, because they avoid these problems to some extent by simultaneously considering the relationship of several species' distributions to more than one climatic variable (Iversen, 1944; Fauquette et al., 1998; Pross et al., 2000). However, these methods still ignore climatically relevant information in the proxy data, notably in terms of species assemblages and species abundances.

Multivariate statistical approaches developed during the last three decades provide the most powerful approach. Transfer function equations are derived by multivariate techniques from an adequate calibration sample of modern distributional data, and applied to paleo-samples to estimate environmental

parameters (Birks, 1995). Although the basis of these methods remains the same, several different methods have been developed over the last few decades for establishing and then inverting the pollen–climate relation.

Estimates of past climates may be obtained for a time series of pollen samples obtained from a single site, or several sites from the same region, giving a continuous time series of climate values (Guiot et al., 1989; Seppä and Birks, 2001). With the advent of continental-scale databases of pollen sequences, various studies have examined the spatial extent of climate changes over a wide area (Cheddadi et al., 1997; Sawada et al., 2004). These studies, which require careful correlation between sites (Dating Techniques), have tended to focus on single time periods, classically the mid-Holocene. Given the low spatial resolution of most climate models, this time-slice approach is appropriate for comparing paleo-GCM output with proxy data climate reconstructions.

In order to transform the information contained in pollen assemblages into climatic values, different approaches and different methods have been developed since the 1940s. In this article, we first review the various different types of methods and approaches that exist, followed by a comparison of the strengths and weaknesses of these methods. Finally, we present three case studies showing climate reconstructions at different temporal and spatial scales.

Advantages and Disadvantages of Pollen Data for Climate Reconstructions

There are now a large number of different types of fossil data that can be used in climate reconstructions, including fossil Coleoptera (see Overview), Chironomids (see Chironomid Overview), plant macrofossils (see Dendroarchaeology; Dendroclimatology), and each type has its own strengths and weaknesses.

Among the advantages of pollen data (Moore et al., 1991), some are as follows:

- (1) Information about the presence of taxa, pollen samples provide a quantified idea of the composition of the vegetation around the site.
- (2) The relatively small amount of sediment required for pollen analysis allows studies to be made at a relatively high temporal resolution.
- (3) Although the temporal resolution is lower than most annual proxy archives (e.g., see Dendrochronology; Varved Lake Sediments), most pollen sequences will cover a longer period of time, and hopefully include a greater variety of climatic changes.
- (4) Sites containing a good pollen record are relatively easy to find in humid regions, although this is more problematic in drier regions where pollen preservation is worse.
- (5) Pollen analysis is a well-established method, having been used for well over 100 years, and there is an extensive catalog of existing literature.

The main disadvantages are as follows:

- (1) Due to differences in pollen productivity, transport, and preservation between different taxa, the relationship between the composition of the pollen assemblage and that of the vegetation is extremely complex and nonlinear (see

POLLSCAPE Model: Simulation Approach for Pollen Representation of Vegetation and Land Cover

- (2) The identification of pollen grains is frequently limited by morphological similarities between grains from different species, and often only the genus can be established. This lack of taxonomic information limits the precision available in the reconstructed climate because many genera include species with contrasting climatic limits.
- (3) Different pollen sites record a different sample of the surrounding vegetation due to topographic differences and basin size. Small forest hollows record an extremely local vegetation signal, usually the vegetation within 10–100 m of the site, and a reconstructed climate will be affected by any local microclimate (see [Stand-Scale Palynology](#)). Large lake basins record a regional or even extra-regional pollen signal ([Jacobson and Bradshaw, 1981](#)), and the climate reconstructed will therefore be more similar to a mean regional climate.

Methods Based on Similarity

Mutual Climate Range Methods

The mutual climate range (MCR) methods use climatic limits (e.g., temperature extremes) for presence of pollen taxa, established from the modern distribution of one or several plant species. A possible range of climate values for a given fossil sample is estimated by combining the modern limits of all taxa found (see [Figure 2](#)).

In the simplest approach, a single taxon with a well-defined climatic tolerance is used to estimate a change in climate by its presence or absence. For example, the dwarf birch, *Betula nana*, which does not occur currently in lowland British Isles, is observed in this region during the Late Glacial interval. By establishing that the modern distribution of *B. nana* is

Figure 2 The climatic limits of holly (*Ilex aquifolium*), ivy (*Hedera helix*), and mistletoe (*Viscum album*). Above these limits, the species are not present. Using this diagram, it is therefore possible to estimate past temperatures within a certain range, according to the presence or absence of these three species in a pollen sample. Modified from Iversen J (1944) *Viscum, Hedera and Ilex* as climatic indicators. *Geologiska Föreningen Förhandlingar* 66: 463–483.

limited by maximum summer temperatures over 22 °C, [Conolly and Dahl \(1970\)](#) estimated that during the Late Glacial, the maximum summer temperature in lowland Britain did not exceed 22 °C, compared to a modern value of 30 °C.

A better constraint can be obtained by using two environmental variables and/or several species in parallel. Using the present-day distribution of ivy (*Hedera helix*), holly (*Ilex aquifolium*), and mistletoe (*Viscum album*), constrained by specific winter and summer temperatures, [Iversen \(1944\)](#) estimated the climatic changes of the mid-Holocene in Denmark to within a defined range, showing an increase of 2–3 °C in summer temperature and an increase of 1–2 °C in winter temperatures ([Figure 2](#)).

The complexity can be increased, for example, using climatic envelopes defined with many environmental variables and for larger sets of taxa. In order to reconstruct the climate for a fossil sample, the envelopes for all taxa present are superimposed and the resulting overlap is considered to be the possible paleoclimatic range ([Figure 3](#)). The method has been applied to pollen data from northeastern Australia by [Kershaw and Nix \(1988\)](#), showing warmer and wetter conditions during the mid-Holocene.

In order to improve the methods, [Fauquette et al. \(1998\)](#) have made use of the taxa abundances to refine the climatic range identified by the presence of a given pollen taxon, by defining a set of abundance classes. For example the elm, *Ulmus*, is considered to be present at 0.5%, with an annual temperature range between -3 and 22 °C. Once the percentage passes a defined threshold, the taxon is considered to be abundant, and the climatic range is reduced (*Ulmus* is considered abundant over 8%, and the annual range shrinks to between 4 and 17 °C).

Figure 3 Synthetic mutual climatic range diagram. Three species' climatic ranges are shown. A sample containing all three of these species is assumed to have climatic envelope defined by the overlap of the three ranges.

Finally, Pross et al. (2000) have improved on the method in order to further narrow the climatic ranges obtained. Climatic ranges were reconstructed for a set of synthetic but possible pollen assemblages and compared against the actual modern climate for that synthetic assemblage. Because the actual modern climate range for a given assemblage is narrower than the potential climate range predicted by pure indicator principle, they conclude that the MCR technique exaggerates the ranges and they take into account actual ranges to obtain the most likely climatic intervals.

Because MCR methods do not depend on a relation between modern taxa assemblages and climate values, they work well when the vegetation composition has no modern analog. However, the distributions of one or more taxa in climate space may be discrete and no overlap occurs. This is usually due to a lack of modern distributional data, and will bias the estimates obtained.

Modern Analog Technique

The modern analog technique (MAT) (Guiot, 1990; Jackson and Williams, 2004) uses a large data set of modern pollen samples, and consists of selecting a set of modern samples (or analogs) that most closely resemble each fossil pollen sample. The resemblance is assessed by comparing modern and fossil pollen assemblages in terms of taxa composition and abundance. In most studies, the dissimilarity between assemblages is quantified using squared-chord distances, which consist of a prior transformation of pollen percentages by taking the square root in order to reduce the influence of the few relatively abundant taxa in the samples (Figure 4).

Once a set of modern analogs has been selected, climatic values can be attributed to the fossil sample as a weighted average of the climate of the modern samples. Climatic

estimates at the exact location of each modern pollen-sampling site are obtained by interpolation from a set of meteorological stations. The weights used are the inverse of the chord distance, which allows the most similar analogs to have the greater influence on the climate estimates obtained. The number of analogs chosen is usually fixed at the start of the analysis, but Waelbroeck et al. (1998) suggested using the analog distances: when a sharp increase in distance occurs, no further analogs are selected. Using a modern data set of 227 samples and this method, Guiot et al. (1989) reconstructed annual temperature and precipitation from two long cores from central France, and provided climatic time series that cover the last 140 ka, including both the start and end of the last glacial interval.

The MAT suffers from a number of problems, including assemblages containing taxa that respond to different climatic parameters, the estimation of errors, and dealing with intervals in which the past vegetation has no modern analog. As with the MCR methods, a number of adaptations and improvements have been made to deal with these problems.

In order to deal with the problem of taxa responding to different climatic parameters, Guiot (1990) have used 'bioclimatic' loadings to preferentially weight the distance calculated between the modern and fossil samples. An ordination is made of the modern samples, and the distribution of taxa are examined in order to identify the axis that is most strongly related to the climatic parameter under investigation. The taxa scores along this axis are then used as weights.

The error involved in assigning climatic values is usually estimated from the dispersion of the chosen analogs around the weighted average. This method has the advantage of considering the higher and lower errors separately, resulting in nonsymmetric and more realistic error bars; however, in doing so the total error is underestimated. Nakagawa et al. (2002) have proposed an improved method that uses a linear relationship calculated between observed and estimated climate values at modern pollen sites. The confidence intervals obtained for the linear relation are then applied to past estimates. This requires a dense network of meteorological stations and may not be practical in all regions.

One significant problem for the MAT technique is situations where no good modern analog can be found for a fossil assemblage. These no-analog situations result from vegetation dynamics, anthropogenic influence and lack of adequate modern samples. Davis et al. (2003) proposed a modification to the technique to help avoid this problem, whereby the modern and fossil assemblages were regrouped into plant functional types (PFTs), and analog matching is carried out on the basis of the PFT abundances (scores). Because each PFT represents a set of ecologically similar plant taxa (Prentice et al., 1996), the assumption can be made that a similar climate will always contain a similar composition of PFTs, even if the species composition may vary for nonclimatic reasons.

To further improve the method, information derived from a second climate proxy may be used to constrain the climatic estimates. Cheddadi et al. (1997) estimated paleoclimate from pollen data using MAT constrained with lake-level data. The constraint consists of restricting the set of modern pollen samples considered as analogs of the fossil samples to those locations where the implied change in annual precipitation minus evapotranspiration ($P - E$) is consistent with the regional change in

Figure 4 Synthetic diagram of the modern analog technique. The samples are compared according to the percentage abundance of two taxa. In this example, the fossil sample (red) is closest to five samples, and the climate to be assigned will be a weighted average of the climate associated with these five samples. Sample S2, being the most similar, will have the greatest weight in the estimation.

moisture balance as indicated by lake-level data (see [Overview](#)). The constraint led to an improvement in the spatial coherency of the reconstructed paleoclimate anomalies, especially for P – E. The use of a second proxy as a constraint has the disadvantage that it can no longer be used to independently verify the results; however, if the climatic response of the proxy is well understood, this can offer a more consistent set of results.

One of the principal advantages of the MAT method is that it is well adapted to large data sets, and has been extensively used for large-scale reconstructions ([Cheddadi et al., 1997](#); [Sawada et al., 2004](#)), in part because it does not rely on a response function dominated by a single climate variable, and thus allows reconstructions in areas where the composition of plant communities is limited by different parameters. Recent work by Telford and co-workers, however, has shown that the apparent better performance of MAT, when compared to the calibration methods listed below, may be overexaggerated by lack of full statistical independence and spatial autocorrelation of the climate variable.

Response Surface

The analogs described above do not always provide an adequate set of climatic indicators. To emphasize the signal to noise ratio, [Bartlein et al. \(1986\)](#) proposed a method in which the pollen assemblages are projected onto an environmental space formed by the climatic parameters of interest. Surfaces are then fitted to the abundance values of a set of selected taxa by locally weighted regression ([Cleveland and Devlin, 1988](#)). Having fitted response surfaces for the suite of taxa that will be used to make the reconstructions, the values for the taxa at each grid point can be combined to provide a series of assemblages that may be considered as potential analogs for each fossil assemblage. Thereafter the procedure is very similar to that used in direct quantitative analog methods, with the five to ten closest matching assemblages for each fossil assemblage being identified and used to provide a reconstruction and associated confidence intervals. Due to limited interpolation and extrapolation, response surfaces are less affected by the problem of no-analog vegetation. However, the smoothing of the relation between taxa abundances and climate can lead to an underestimation of true paleoclimate values ([Figure 5](#)).

Webb et al. (1993) have used this technique to estimate seasonal temperatures and annual precipitation across eastern North America for several time intervals since the Last Glacial Maximum (LGM), and have shown that, given an adequate data set, large-scale climatic gradients, and the changes in those gradients, can be reconstructed from pollen data.

Methods Based on Calibration

In contrast to the methods based on similarity, those based on calibration establish a mathematical function (a transfer function, Webb and Bryson (1972)), which relates taxa abundances to climate parameters, and so allows estimates of past climatic conditions. Reconstruction using a transfer function takes place in two stages. In the first, a response function is established ($X = R(C,D)$), which links the abundance of the pollen taxa (X) to a set of climatic (C) and nonclimatic (D) controlling factors. If the climate is considered to be the major

Figure 5 Example response surface. The response surface is fitted to two climate parameters: winter temperatures (MTCO) and summer temperatures (MTWA). The example taxon has its highest abundances at high summer and intermediate winter temperatures.

controlling factor, then the full response function can be approximated to ($X = R(C)$). Once the response function is established, it may be used for past reconstructions by inverting the function to give the transfer function ($C = T(X)$). As before, a number of techniques exist, which are characterized by the method in which the response function is constructed, and below we describe how the response functions for three of these methods are established, followed by a comparative study ([Lotter et al., 2000](#)). This is followed by a description of the use of non-linear neural networks. For further detail, the reader is referred to [Birks \(1995\)](#) and the chapter on reconstruction methods (see [Approaches](#)).

Partial Least Squares Analysis

Partial least squares (PLS) analysis is a modified principal components analysis (PCA) that forces the first axis or component to maximize the covariance between one environmental variable and a linear combination of taxa abundances, thus forming a direct link between the taxa and a single climatic parameter ([Figure 6a](#)). Subsequent components may also be included to further maximize the covariance, but these are constrained to be orthogonal to the preceding component and therefore uncorrelated. If this technique is used with several environmental parameters, it is known as canonical correspondence analysis, and has been used in pollen-based climate reconstructions by Webb and Bryson (1972).

Weighted Averaging and Weighted Average – Partial Least Squares

The preceding method assumes a linear relationship (ascending or descending) between taxa abundances and climatic parameters ([Figure 6a](#)). Although a linear response may be assumed over small ranges of climatic parameters (i.e., short

Figure 6 Two possible response functions. (a) Linear; (b) unimodal.

environmental gradients), a more realistic ecological response function is the unimodal relationship (Figure 6b), in which taxon abundance varies across the environmental gradient, with an optimum at a particular value. The technique of weighted averaging (WA) (ter Braak and Looman, 1986) allows these unimodal response functions to be used in climatic reconstructions, and is considered as the unimodal equivalent of linear regression and calibration (Birks, 1995).

The regression step of WA consists of estimating the response function for a group of selected taxa for a given climatic or environmental parameter. For this, all the modern samples where that taxon is present are used, and the optimum is estimated as the average of the climate of these samples, weighted by the abundance of the taxon. Once established, the past climate parameter is estimated as the weighted average of the optimum of all taxa present in a fossil sample, where the weights are the abundances. The estimates obtained suffer from edge effects, which cause underestimates of extreme values. A correction for this has been proposed by ter Braak and Juggins (1993). As before, errors are calculated by bootstrapping (Efron and Tibshirani, 1993). The main advantages of the WA method are that it uses a theoretically robust response model and copes well in no-analog situations. However, the method may be affected by an uneven distribution of the modern sites along the environmental gradient. Further, any extra indirect covariance between the taxa and the environment is ignored, once the climate variable is taken into account.

Weighted average–partial least squares (WA-PLS) avoids this latter problem by allowing further components to be chosen, as in PLS above, which (1) improve the covariance between the weighted averages and the climate; and (2) must

be orthogonal to the preceding component. These secondary components represent other environmental factors that constrain the composition of a given pollen assemblage (ter Braak and Juggins, 1993).

In a high-resolution study of lake sediments, Lotter et al. (2000) have tested and compared the use of PLS, WA, and WA-PLS for the reconstruction of summer temperatures at Gerzensee, Switzerland. A modern pollen data set of 126 samples was used to establish the transfer functions, which were subsequently applied to 118 fossil samples covering the Late Glacial interval. Although root mean squared error of prediction (RMSEP) tests on the modern data set showed WA-PLS to outperform PLS and WA, the differences were slight. Paleotemperatures reconstructed using WA-PLS temperatures covered a larger range than the other techniques, but all methods showed comparable values, particularly when the errors were taken into account. Lotter et al. (2000) suggest that, although the gradient of temperatures covered by the modern data set was large, the set included both taxa which had an optimum outside of the gradient, indicating a linear approach, and taxa whose optima were included in the gradient, indicating a unimodal approach. Finally, a consensus curve was calculated by using all the predictions for the study of Late Glacial climate change. The temperature curve obtained corresponded well to an oxygen isotope curve from the same site, but showed lags in the response of vegetation to the climatic changes.

Artificial Neural Networks

Artificial neural networks (ANNs) are used for a large variety of nonlinear problems and so lend themselves well to the problem of calibrating pollen assemblages and climatic variables. The classic forward-feed backpropagation network has been used in reconstructions for several proxy–environmental data sets (e.g., pollen, tree rings, diatoms). Generally the networks consist of a set of input nodes, which correspond to each taxon, a hidden layer of nodes and a set of output nodes, which correspond to the climatic parameters (Figure 7). The number of nodes in the hidden layer may vary, depending on the level of complexity required. Each hidden node is, in fact, a coefficient, which is adjusted during a period of training using modern samples and their corresponding climate, until the assemblages can be best transformed into climate. As with the MAT method, ANNs require a large modern data set so that they may be accurately trained. Once the network is established, it can be used to estimate past climates, by entering the taxa abundances found in fossil samples. The method has been used in a climatic reconstruction for a number of European pollen sites at the LGM by Peyron et al. (1998) to give a spatially coherent picture of the conditions of this interval, with a marked northwest–southeast gradient between an extremely cold and dry northwest to milder, although still cold and dry, southeast.

Examples of Paleoclimate Reconstruction from Pollen Data

The methods described above have been applied in a wide range of different regions of the world and in applications at different scales of time and space. Here, we review three recent studies that cover different scales, albeit limited to the

Holocene Epoch: a high temporal resolution study from a single site, mapped climate changes for a continent, and a continual regional reconstruction for the last 12 ka.

Single Site/Time Series

Seppä and Birks (2001) used WA-PLS to reconstruct changes in summer temperature and annual precipitation for a core taken from Lake Tsuolbmajavri in northern Finland. The transfer function was set up using a data set of 304 modern pollen samples from Norway, Finland, and northern Sweden, covering a gradient of approximately 10 °C summer temperature and 2500 mm annual precipitation. A two-component WA-

PLS model was chosen, which, after cross-validation, showed RMSEP errors of about 1 °C and 340 mm and a coefficient of determination (r^2) over 0.7.

Summer temperature and annual precipitation were reconstructed along the core at a resolution of ca. 70 years, covering the last 10 ka (Figure 8). The reconstruction, which began with a cool and moist early Holocene, showed clearly the Holocene thermal maximum between ca. 8.2 and 5.7 ka BP, with temperatures that were up to 2 °C warmer than the present day. The latter part of the Holocene shows a return to cooler and more humid conditions. Seppä and Birks (2001) have linked these changes to large-scale changes in the atmospheric circulation across Fennoscandia, with the warm mid-Holocene

Figure 7 A backpropagation forward-feed neural network with one hidden layer. At the left of the diagram is the input vector. Each input vector represents one pollen sample with, here, five taxa. These abundances are then iteratively related to the output vector, the climate parameter of interest.

Figure 8 Reconstructed summer temperature from Tsuolbmajavri in northern Finland. Modified from Seppä H and Birks HJB (2001) July mean temperature and annual precipitation trends during the Holocene in the Fennoscandian tree-line area: Pollen-based climate reconstructions. *The Holocene* 11: 527–539.

conditions resulting from the establishment of anticyclonic conditions, in turn caused by the loss of the Fennoscandinavian ice sheet and higher summer insolation. The later cooling follows the reduction in insolation in the later Holocene.

Time-Slice/Spatial Study

To provide data for comparison with the output of an atmospheric GCM, Sawada et al. (2004) estimated the change in summer temperatures for the North American continent at 6 ka BP. Such 'time-slice' reconstructions at large spatial scales have become increasingly feasible, due to the establishment of continental-scale databases of modern and fossil pollen samples (see [Databases and Their Application](#)). The training data set consisted of 4590 pollen samples, and associated temperature values, distributed across the continent, and samples from 545 sites were available for the mid-Holocene. A modified MAT technique was

used to estimate temperature at each of the fossil sites. The modifications consisted of an increase in the number of taxa used to match samples and attempts to more objectively identify both poor analogs and the number of analogs to be used.

The results for the 545 sites were interpolated onto a gridded surface, and then the amount of change in temperature values (i.e., the anomaly) between 6 ka and the present was calculated by subtracting the mid-Holocene surface from an interpolated modern climate. The results ([Figure 9](#)) showed a general trend from a warmer north to a cooler south, albeit with a number of local differences such as a slight cooling in central and north-western Canada. The warming in the north has been linked directly to the increased insolation during the mid-Holocene. However, Sawada et al. (2004) suggest that the southern cooling may result from an inadequate set of modern samples. Mid-Holocene cooling at mid-latitudes has also been observed in previous continental scale studies from both North America

Figure 9 Map of summer temperature anomalies for the North America continent at 6 ka BP. Reproduced from Sawada M, Viau A, Vettoretti G, Peltier WR, and Gajewski K (2004) Comparison of North American pollen-based temperature and global lake-status with CCMA AGCM2 output at 6 ka. *Quaternary Science Reviews* 23: 225–244, Copyright 2004, with permission from Elsevier.

(Gajewski et al., 2000) and Europe (Cheddadi et al., 1997), and appears to be a consistent feature of Holocene climate change.

Continuous Holocene Study

Time-slice reconstructions are static, in the sense that each time period is considered separately. By combining the site-based approach with the time-slice approach in order to improve the signal-to-noise ratio, Davis et al. (2003) introduced an approach in which the regional large-scale changes are considered in a continuous way, allowing an investigation of the evolution of large-scale climate. Again, this study relies on the existence of continental-scale databases.

The study used a modern data set of 2363 samples distributed across Europe and North Africa. These were used to estimate temperature parameters (summer, winter, and annual) for each sample of Holocene age from a set of 510 sites, giving approximately 68 000 climate estimates distributed across Europe and throughout the last 12 ka. Estimates were made using a modified MAT method, in which pollen taxa were classed into vegetation groups to limit the no-analog problem. These were interpolated onto a regular grid in both time and space and then area-averaged into six regions.

The results (Figure 10) showed quite different dynamics of temperature change in the various regions of Europe. Notably, the Holocene thermal maximum appears confined to Northern

Figure 10 Annual temperature anomalies for six regions of Europe. The inset shows the geographical limits of the regions. Reproduced from Davis BAS, Brewer S, Stevenson AC, Guiot J, and Data Contributors (2003) The temperature of Europe during the Holocene reconstructed from pollen data. *Quaternary Science Reviews* 22: 1701–1716, Copyright 2004, with permission from Elsevier.

Europe, while in the south, temperatures decreased during the early Holocene and remained cooler than present for much of the period. This suggests that the cooler mid-latitudes observed in the spatial studies of mid-Holocene climate (see above) are not anomalous, but instead form part of a general opposing trend of temperature changes between the north and south.

Perspectives

Perhaps the greatest problem facing paleoclimate reconstructions today is that the distribution of the vegetation is assumed to be uniquely controlled by the climate, and nonclimatic parameters, for example, CO₂ concentration or soil depth, are not taken into account. During intervals of substantial changes in these parameters, for example, the last glacial interval, it may be expected that their effects on the vegetation composition may bias any paleoclimatic reconstruction. Vegetation models are the only existing tool that allow the CO₂ effect to be taken into account, and there is therefore interest in using the models for climatic reconstruction, by inverse modeling of pollen data. This approach uses a vegetation model to explore a large number of possible climatic scenarios in order to find the scenario that corresponds to the vegetation observed in a fossil pollen sample (Guiot et al., 2000). Past changes in CO₂ may be set in the model, allowing this bias to be reduced. Work on this approach, together with improvements in our knowledge of the variations of nonclimatic factors, will help to provide more robust future reconstructions.

Acknowledgments

The authors are grateful for helpful discussions with people working in the field of paleoclimatic reconstructions, including John Birks, Rachid Cheddadi, Basil Davis, Steve Juggins, Odile Peyron, Heikki Seppä, Pavel Tarasov, and Jack Williams. We would like to thank Heikki Seppä for access to the data in Figure 8, Mike Sawada for access to Figure 9, and Yannick Garcin for help with all the figures.

Reconstructing Past Biodiversity Development

B V Odgaard, University of Aarhus, Aarhus, Denmark

© 2013 Elsevier B.V. All rights reserved.

Introduction

Concerns for the preservation of modern biodiversity in light of climate change and increasingly intensive land use, erosion, and human interference with ecological systems have led to stronger interest in the geological record of changes in past biodiversity. The concept of biodiversity includes genetic variation and variation in species and ecosystem composition. Although exciting progress has taken place recently in our understanding of past genetic diversity (see [Ancient Plant DNA](#)), most paleoecological data record species associations or higher levels of organization of individuals. The most widely available type of paleoecological data is pollen, which, in this discussion, also includes tracheophyte and bryophyte spores that are usually counted during pollen analysis.

Measuring Biodiversity

Following [Whittaker \(1977\)](#), vegetation diversity may relate to communities (alpha diversity), landscapes (gamma diversity), or regions (epsilon diversity). Similarly, changes between communities (beta diversity) or between landscapes (delta diversity) can be defined. Such scales are useful also in a paleoecological context where pollen data – depending on the size of basin – broadly reflect the alpha to epsilon diversities ([Figure 1](#)). In contrast, because of their shorter distance of transport, plant macrofossils mostly reflect the alpha and beta levels of diversity of past vegetation.

The most obvious aspect of vegetation diversity is species richness, which is simply the number of species. In a community of limited extent, the number of plant species may be rather accurately enumerated, but in larger areas, usually only a sample of the total species richness can be investigated. However, the relation between species richness of the sample and that of the entire area is not simple. This is because not only the species richness of the entire unit of vegetation but also the relative frequency of each species is important for how many species are recorded in the sample. In other words, sample species richness is also dependent on evenness. Evenness is a measure of the distribution of individuals for each species (the relative frequency of species). A community in which all species have the same number of individuals (are equally common) is said to have maximum evenness, while any other combination of frequencies results in lower evenness ([Figure 2](#)). As more individuals are registered in a sample, the number of species or taxa grows, a relationship that is depicted in so-called species growth curves. Evenness determines the shape of such species growth curves: it is steep when evenness is high and more gradual when evenness is low ([Figure 3](#)). This means that if evenness is at a maximum, then all species are likely be represented in even a small sample comprising only a few percent of the individuals of the community. In contrast,

if evenness is very low, then only a fraction of the species present in the entire population is likely to be found in even a large sample comprising almost half the individuals of the community.

Many diversity indices have been developed; most of them are composite measures of species richness and evenness. Several of these indices have been applied to fossil records. As explained above, even species richness is influenced by evenness, unless the total species richness of the entire population is recorded. A useful index of evenness is

$$E_{1/D} = \frac{1 / \sum_{i=1}^S p_i^2}{S}$$

where p_i is the proportion of taxon i and S is the total number of taxa in sample. $E_{1/D}$ is independent of richness and theoretically ranges from almost zero (when one taxon is very dominant) to one at maximum evenness ([Smith and Wilson, 1996](#)).

Biases in Fossil Records of Biodiversity

There are three obvious biases when using samples of fossil assemblages as reflections of past biodiversity: taxonomic precision, sample size, and pollen productivity.

Taxonomic Precision

Plant macrofossils can often be identified to specific or at least generic level, but pollen can usually only be identified to genus or often only to family level. This lack of taxonomic precision with pollen data causes a nonlinear relationship between the plant species number and palynological richness (number of pollen taxa). This means that the number of pollen taxa in an assemblage cannot be taken as a direct measure of the number of plant species in the vegetation from which that assemblage was derived. With a low number of species, the relationship is almost 1:1, but in rich communities, the relationship may be 2:1 or even higher. [Odgaard \(1994\)](#) found the relationship to be almost identical in three modern communities with different disturbance regimes and used this finding to correct fossil palynological richness for bias in taxonomic precision.

Sample Size and Pollen Productivity

When pollen is analyzed in a sample of a geological deposit, the microfossil count (for instance, 1000 specimens) represents an infinitesimal fraction of the number of pollen grains once produced in the area of interest and during the period of interest ([Figure 4](#)). Because of the small sample-to-population ratio, the evenness of the population (i.e., all the pollen grains from the area and period of interest) is theoretically important for how many microfossil types (taxa) are found in the sample.

The fact that the observed number of taxa increases with sample size (Figure 3) has led to the common notion that if taxon numbers are to be compared between samples, then the number of individuals in each sample should be identical. Because it is often impractical to tally exactly the same number

of individuals in each sample, especially during pollen counting, some technique is needed to estimate the number of taxa that would have been found in a sample if a lower count had been made. Rarefaction is such a technique. However, it is very important to note that rarefaction does not allow extrapolation to taxon numbers in a larger sample, only estimation of taxon numbers at lower counts than the actual.

Developed in the late 1960s and early 1970s, rarefaction was introduced to paleoecology in the 1970s (Tipper, 1979). It was first used in Quaternary pollen analysis in the 1980s (Birks and Line, 1992; Birks et al., 1988). Intuitively speaking, rarefaction uses the information of frequency of each taxon in an assemblage to estimate at what lower count than the actual count a taxon would be represented by its first individual. For example, a taxon with a frequency of 5% (one out of 20) would be expected to be found with one individual out of the first 20 individuals counted plus or minus an error term. The rarefaction estimate is defined by

$$E(T_n) = \sum_{i=1}^T 1 - \left[\frac{(N - N_i)!(N - n)!}{(N - N_i - n)!N!} \right]$$

where $E(T_n)$ is the expected number of taxa at sample size n ; N is the population size; T is the number of taxa in population, and N_i is the number of individuals of taxon i . In paleoecology, the population size is not known, and here, the actual number of individuals in the samples is taken as the population size,

Figure 1 Ecological spatial scales of diversity (*sensu* Whittaker, 1977) compared to the spatial scales reflected by paleoecological studies using pollen and plant macrofossils.

while n is the lower number of individuals for which taxon richness is to be estimated.

Rarefaction estimates are often inappropriately interpreted as an index of past species richness. For example, stratigraphic plots of rarefaction estimates based on pollen data tend to be generally parallel to plots of nontree pollen (Figure 5), and this may superficially be interpreted as a reflection of generally higher species richness in nonwoodland communities. It is important to note, however, that such estimates may theoretically be strongly biased by the evenness of the assemblages and by variable population sizes, as well as varying taxonomic precision. The study of Räsänen et al. (2004) provides an

Figure 5 Survey pollen diagram from Holocene sediments from lake Navn Sø, Denmark, showing percentages of pollen from trees (green), grasses and herbs (yellow), and heather (violet), as well as the number of terrestrial pollen types at constant count of 1000 pollen grains. Adapted from Odgaard BV (1999) Fossil pollen as a record of past biodiversity. *Journal of Biogeography* 26: 7–17.

example where rarefaction estimates of palynological richness and evenness of the pollen assemblages correlate significantly, indicating that observed richness is biased by evenness. Furthermore, the underlying assumption in using a constant sample size is that population size is constant throughout the time series, and this is probably only rarely the case. If population sizes vary while sample size is kept constant, the counted fraction of the population varies, and taxon richness may accordingly covary. Odgaard (1999) and van der Knaap (2009) suggested workarounds for the dependence of observed microfossil type richness on population size. Using estimates of relative (Odgaard, 1999) or absolute (van der Knaap, 2009) pollen accumulation rates, these procedures attempt to estimate the number of pollen taxa that would have been found, provided the same fraction of the pollen population (the pollen production of the area) had been tallied.

Interpreting Records of Sample Diversity

This section gives a few examples of pollen-based biodiversity studies illustrating the use of various approaches and numerical methods.

The Dynamics of Landscape Biodiversity

Smith and Cloutman (1988) studied the development of a 15 ha bog in Wales using pollen records from 13 open sections or cores. The chronology was based on radiocarbon dates. Because of the high number of well-dated pollen stratigraphies in a small area, Smith and Cloutman (1988) were able to reconstruct the Holocene landscape variation of the local vegetation. The pollen records reflected the on-site hydrosereal vegetation as well as the vegetation surrounding the site. The large number of sites allowed an interpretation of the past landscapes into units, such as mixed woodland, hazel woodland, blanket peat, grassland, and dry heath. The time series of reconstructions clearly reflect the decrease of biodiversity at landscape level (gamma diversity) as blanket peat expanded over the area (Table 1).

Controls of Palynological Richness

Peros and Gajewski (2008) studied the number of pollen taxa from arctic nonarctic plants in surface lake sediments from northern Canada and concluded that the latitudinal trend of observed palynological richness, rarefacted to counts of 300 or 100, was opposite to the trend documented for the species richness of the vegetation. This finding suggested that palynological richness in that area is a very poor indicator of landscape scale species richness. Using pollen concentration as a proxy of landscape scale pollen productivity, Peros and Gajewski (2008) also found that palynological richness was negatively correlated to pollen productivity in the same dataset. In contrast, they found a positive correlation between pollen sample evenness and palynological richness (Figure 6). The same relations between palynological richness, concentration, and evenness were found in Holocene samples from the area. Peros and Gajewski (2008) were unable to efficiently separate the effects of pollen productivity and evenness, but their data suggested that pollen productivity was especially effective in controlling palynological richness at low productivity gradients.

The importance of the pollen productivity control of palynological richness was strongly underlined by a recent study by Meltsov et al. (2011). Comparing floristic and palynological richness along an openness gradient in Estonia, Meltsov et al. (2011) found that sediment samples from open vegetation (within 250 m from sediment samples) consistently had more pollen taxa than samples from more wooded surroundings. However, the additional pollen taxa in samples from sites with more open vegetation were widespread pollen taxa, virtually unrelated to local vegetation communities. Also, no relation between pollen sample evenness and palynological richness was found in this study. Furthermore, the majority

Figure 6 Plot of rarefacted palynological richness (base count 100) against pollen concentration and pollen sample evenness (Hurlburt's probability of interspecific encounter) in North American arctic lake surface samples. Reproduced from Peros MC and Gajewski K (2008) Testing the reliability of pollen-based diversity estimates. *Journal of Paleolimnology* 40: 357–368, with permission from Springer.

of species in the vegetation (two-thirds of the local pollen types) were conspicuously absent from the pollen counts ($n > 1600$) of the sedimentary samples.

These results strongly underline the control exerted by overall pollen productivity on the observed pollen sample richness. Because pollen productivity is lower in open landscapes than in densely wooded areas, widespread but less frequent pollen types are more effectively recorded in samples from open landscapes than from closed ones. Rarefaction estimates of pollen sample richness are, accordingly, a complex reflection of many processes such as pollen population evenness, pollen dispersal, landscape pollen productivity, and possibly floristic richness. Although more work is needed to resolve these complexities, pollen productivity seems a much more important control of palynological richness than does floristic richness.

Introduction

Pollen-analytical (palynological) data are counts of different pollen and spore types present in one or more sediment samples. The samples or objects can be from one sediment core collected from the study site (temporal, stratigraphical data) or from one age or depth at several sites (spatial, geographical data). The most common type of spatial data consists of pollen counts from the uppermost, surficial sediments, so-called surface samples. Stratigraphical and spatial data commonly contain counts of many (50–250) different pollen and spore types or taxa in a large number of samples (50–500). Such data are highly multivariate, containing many variables (pollen and spore types) and many objects (sediment samples). In pollen analysis, the number of objects is usually much larger than the number of variables, in contrast to, for example, diatom analysis where the number of taxa usually exceeds the number of samples. With the development of national or continental databases of palynological data, data-sets can also consist of pollen counts from many different cores from a large number of sites over a broad geographical area, thereby combining both temporal and spatial data (Brewer et al., 2012; Mitchell, 2011).

Pollen counts are almost always expressed as percentages or proportions of some calculation or pollen sum (e.g., total terrestrial pollen and spores), thereby transforming the counts into relative proportional or percentage compositional data. The sample sum itself is relatively uninformative in many numerical analyses. It is largely determined by the initial research and sampling design, namely, the number of individual pollen and spores to be counted per sample. Numerical properties of relative palynological data are that the data are ‘closed,’ there may be many zero values (absences) in the data, and there may be many taxa. Closed data require special methods for correct statistical analysis. Reyment and Savazzi (1999) discuss statistical approaches to analyzing closed data involving log-ratios. The large number of zero values can, however, cause problems in the use of log-ratios. Pollen counts are more rarely expressed as pollen concentrations (grains per unit volume (grains cm^{-3}) or dry weight of sediment (grains gm^{-1})). If the sediment matrix accumulation rate (net thickness of sediment accumulation per unit time; cm year^{-1}) can be determined by, for example, age-depth modeling, pollen accumulation rates (PAR) (‘pollen influx’; $\text{grains cm}^{-2} \text{year}^{-1}$) can be estimated. Such ‘absolute’ data are harder to obtain than relative counts. Although their statistical properties are less complex than relative data, absolute data have a high inherent variance and some variance-stabilizing transformation is usually essential prior to numerical analysis (Birks and Gordon, 1985).

A pollen count is a statistical *sample* count of the total amount of pollen present in the sediment level of interest. This count is an estimate of the underlying statistical *population* of interest. Despite the technique of Quaternary pollen analysis being nearly 100 years old, the relevant statistical methods for

assessing the inherent statistical uncertainties attached to pollen counts were only relatively recently developed by J.E. Mosimann, L.J. Maher, and K.D. Bennett. The application of multivariate data-analytical techniques such as cluster analysis and principal components analysis (PCA) to pollen-analytical data began in 1970 through the pioneering work of D.P. Adam, M.B. Dale, D. Walker, H.S. Cole, T. Webb III, E.J. Cushing, A.D. Gordon, and others. Since then, the use of statistical procedures and multivariate numerical techniques has increased greatly (Birks, 1992; Birks and Gordon, 1985) for data collection and assessment, data summarization, data analysis, and data interpretation.

Numerical methods are useful tools at many stages in a palynological investigation. During data collection, they can be invaluable in identifying certain morphologically similar pollen types. In data assessment, statistical techniques are essential in estimating the inherent errors associated with the resulting pollen counts. A range of numerical techniques can be used to detect and summarize major underlying patterns in palynological data. For single stratigraphical sequences, the numerical delimitation of pollen-assemblage zones can be an important step in data summarization. Other numerical techniques such as ordination procedures can summarize temporal or spatial trends in one or several data-sets. Numerical methods are essential for quantitative data analysis in terms of estimating palynological richness, detecting population changes, modeling population responses, quantifying rates of change, detecting temporal patterns such as periodicities and power spectra in time series, and reconstructing quantitatively past climate. The final stage of data interpretation can be greatly aided by numerical techniques in the reconstruction of past vegetation and in the testing of competing hypotheses about underlying causative factors such as climate change and human activity in determining pollen-stratigraphical changes. As broader and more complex questions are asked of palynological data, numerical methods are being constantly updated and modified in an attempt to help answer new research questions (Birks, 2012a).

The ability to interpret output from computer-based numerical analyses (e.g., PCA) in a rigorous and critical way both numerically and palynologically requires that the investigator has a good understanding of the underlying mathematical theory and the biological and geological assumptions of the numerical methods being used. Table 1 lists valuable texts about many of the relevant numerical methods used with palynological data. Table 2 lists texts about numerical techniques in pre-Quaternary deep-time geology, paleoecology, and paleobiology, many of which are relevant in the quantitative analysis of Quaternary palynological data. The texts listed in Tables 1 and 2 are valuable introductions to many of the numerical methods that form part of the tool kit for Quaternary pollen analysis in the twenty-first century.

Because of space limitations, references to primary sources are mainly restricted to publications not covered in the reviews

by Birks and Gordon (1985), Birks (1987, 1992, 1995, 1998), Birks and Seppä (2004), and Birks et al. (2010). Many of the numerical methods discussed here are also widely used in paleolimnology (Birks, 1998, 2010). The recent book edited by Birks et al. (2012) provides up-to-date reviews of the numerical and statistical techniques used in paleolimnology, many of which are directly relevant to the analysis of Quaternary palynological data.

Data Collection and Data Assessment

Numerical tools can help in the identification of fossil pollen types and hence in basic data collection. Statistical techniques are essential in the assessment of the statistical uncertainties associated with pollen counting, namely, error estimation.

Identification

Pollen identification depends on careful comparison of fossil material with modern reference material prepared and mounted in the same way as the fossil material. Pollen identification involves assigning fossil grains to preexisting categories of modern taxa. With experience, most grains in a temperate flora can be assigned by memory to modern categories. However, some numerically dominant and ecologically important pollen types may be so similar in overall morphology and appearance that the pollen analyst cannot consistently assign a particular fossil to a modern species. This problem is particularly acute with pollen from several important tree or shrub genera, such as *Pinus* (pine), *Picea* (spruce), and *Betula* (birch). Pollen from these taxa is often a substantial component in pollen assemblages from northern temperate and boreal regions. In such cases, numerical techniques can be invaluable in distinguishing the pollen to lower (species or subgenus) taxonomic levels, thereby enabling subsequent data analysis to capture more of the ecological signal encoded in the assemblage. Pollen-morphological characters are often of different data types (e.g., quantitative measurements, ordinal or multi-state qualitative (e.g., smooth, rough, and very rough), binary or dichotomous (e.g., presence or absence of granules)). If possible, all the available characters should be used in an attempt to achieve reliable identifications. Numerical techniques such as the deviant index for mixed data (Hansen and Cushing, 1973) and classification and regression trees (CART) (Lindbladh et al., 2002) have proved to be powerful means of identifying fossil pine and spruce grains to species level.

Pollen counting and identification are very time-consuming and efforts are continually being made to automate them (Flenley, 2003) using texture measures, artificial neural networks, Gabor transforms, digital moments, and other pattern description and recognition techniques. Major advances are currently being made at Massey University, New Zealand, in automated pollen identification and counting using Classifynder (Holt et al., 2011; <http://www.classifynder.com>). Within a few years, automated pollen analysis will be frequent in many palynological laboratories.

Error Estimation

A pollen count is a sample, hopefully an unbiased sample count, of the total amount of pollen preserved in the sediment sample of interest. As in all sampling, there are statistical uncertainties associated with any sample count. The larger the pollen count, the smaller the uncertainties become. As larger counts require more time to obtain, there is a trade-off between time and level of uncertainty. It is therefore important to estimate the uncertainty associated with all pollen counts (Bennett and Willis, 2001; Maher et al., 2012).

Methods for estimating counting errors and confidence intervals associated with relative pollen data are well developed and are based on the multinomial and negative multinomial distributions (Mosimann, 1965). Errors depend on the size of the count and on the proportion in the count sum of the pollen type of interest. The degree of uncertainty decreases with the size of the count. Methods for estimating errors and confidence intervals associated with pollen concentrations are also available (Maher et al., 2012). Estimating the total error requires careful propagation of errors associated with the various steps involved in deriving concentration values. The total error depends not only on estimating and combining these errors but also on the number of fossil grains counted. Estimating the errors for PAR is similar to estimating concentration errors but with the additional complexity of incorporating the uncertainties associated with estimating sediment accumulation rates based on radiocarbon dates and calibrating radiocarbon ages into calibrated ages (Maher et al., 2012). The total error associated with PAR may be 25–40% or more of the estimated values. It is therefore essential to derive and display reliable estimates of the total errors before attempting interpretation of observed changes in PAR (Bennett and Willis, 2001).

Data Summarization

This involves detecting the major patterns of variation within a single data-set (stratigraphical or geographical data) and the patterns of similarity and difference between two or more stratigraphical sequences or geographical data-sets.

Single Data-Sets

A useful first step in the numerical analysis of a multivariate palynological data-set is to summarize the data as a few groups or in a few dimensions. These are selected to fulfill predefined mathematical criteria, such that the groups maximize the between-group variance or the selected dimensions and axes capture as much of the total variance in the data with the constraint that all the axes are uncorrelated to each other. However, standard techniques for clustering or partitioning (e.g., hierarchical cluster analysis, *K*-means clustering, two-way indicator species analysis) and ordination or dimension reduction (e.g., PCA, correspondence analysis (CA), detrended CA (DCA), principal coordinates analysis, nonmetric multidimensional scaling (NMDS)) do not take account of the stratigraphical or geographical nature of the data. Hence, one may discard potentially important information when these methods are applied to palynological data, with the result that objects with similar pollen composition may be grouped together even though the objects are far apart stratigraphically or geographically. Numerical methods that take account of stratigraphical or geographical information include constrained clustering and partitioning (one-dimensional constraints for stratigraphical data; two-dimensional constraints for spatial data) and constrained ordination (redundancy analysis (RDA)=constrained PCA, canonical CA (CCA)=constrained CA, detrended CCA (DCCA)=constrained DCA). Detailed accounts of these methods are given in Gordon

(1999), ter Braak (1996), Legendre and Legendre (1998), and Legendre and Birks (2012a,b).

Stratigraphical sequences are most commonly summarized as a series of local or site pollen-assemblage zones. Numerical zonation is implemented by stratigraphically constrained clustering or partitioning using an agglomerative or divisive algorithm (Birks, 2012b; Birks and Gordon, 1985) followed by a comparison of the variance of the zones with the variance expected under the broken-stick model to provide a basis for deciding how many zones should be defined (Bennett, 1996). Of the many constrained clustering and partitioning techniques currently available, optimal partitioning using the sum-of-squares criterion and implemented by a dynamic programming algorithm (Birks, 2012b; Birks and Gordon, 1985) is consistently the most robust and hence most useful numerical zonation procedure.

Ordination of stratigraphical data, constrained by object depth or age, by RDA, CCA, or DCCA can be valuable in identifying the major patterns of variation or latent structure, the nature of change, and any trends in the sequence (Birks, 1987). For some research questions, it may be useful not to impose the stratigraphical constraint and to use PCA, CA, DCA, etc., simply to detect the major patterns of variation irrespective of the ordering of the objects. In other research problems, it may be useful to partial out, as covariables, the effects of 'nuisance' variables that are not of primary interest (e.g., Bradshaw et al., 2005; Odgaard, 1994) in partial PCA, CA, DCA, RDA, CCA, or DCCA. Methods based on an assumed linear response of the variables to the underlying latent gradients of variation implicit in PCA and its relatives (RDA, partial PCA, partial RDA) are appropriate with palynological data (stratigraphical or spatial) with a total compositional turnover of 2 or less standard deviations as estimated in DCA or DCCA (ter Braak, 1996). Methods based on an assumed unimodal response model implicit in CA and its relatives (DCA, CCA, DCCA, and their partial relatives) are most appropriate with data showing a high total compositional turnover (>2 standard deviations). Plotting the ordination results (object scores) in a stratigraphical context can provide a useful summary of the major patterns of variation and the nature of changes in the sequence and allows the detection of trends and abrupt changes within the sequence which may be obscured in zonation with its primary concern on partitioning the data sequence into 'homogeneous' units or zones. Careful examination of the taxon (variable) scores can also reveal which pollen taxa are most influential to the object scores for a given ordination axis, thereby providing an ecological interpretation of the observed patterns of variation (Birks, 2012b).

Since the pioneering uses of NMDS in Quaternary palynology (Birks and Gordon, 1985), NMDS is being increasingly used by Quaternary pollen analysts. NMDS produces a low-dimensional representation or map of the objects (pollen samples) (like PCA and CA) but where the rank orders of the similarities between all pairs of objects in the original full-dimensional data are represented monotonically in the low-dimensional ordination plot. There is no unique solution and no underlying response model in NMDS in contrast to PCA or CA. NMDS simply produces a low-dimensional representation or map of the objects. Interpretation in terms of the pollen taxa is often difficult and can involve plotting taxon values on the

resulting ordination plots. There is no guarantee that the NMDS axes are capturing the major patterns of variation or latent structure in the data, in contrast to PCA and CA. Overall, it has few advantages over PCA or CA as a tool in data summarization (see Legendre and Birks, 2012b; Prentice, 1980).

In the analysis of geographical palynological data, spatial constraints can be incorporated in clusterings or partitionings based on cluster analysis (Legendre and Birks, 2012a; Legendre and Legendre, 1998) and in ordinations (Legendre and Birks, 2012b; ter Braak, 1996). The question of whether to apply such constraints depends very much on the research problem of interest – do similar modern pollen assemblages all occur together geographically, or how can modern pollen assemblages be partitioned into coherent geographical areas of similar pollen composition? In the first case, unconstrained analysis would be appropriate; in the second case, constrained analysis would be required. The results of clusterings and ordinations should be displayed as maps of the group membership of objects or object scores on the first few ordination axes (Grimm, 1988). The appropriate number of ordination axes to retain can be assessed by comparison with the broken-stick model (Legendre and Birks, 2012b; Legendre and Legendre, 1998).

CART are useful tools in the analysis of sets of modern pollen assemblages. They describe the dependence of response variable values on the values of predictor variables. They are defined by a recursive binary partitioning of the data-set into subgroups that are successively more and more homogenous in the values of the response variable. At each partition, one predictor is used to define the binary split, and the split that maximizes the homogeneity and difference between the two subgroups is selected. Regression trees can be extended to consider multivariate responses (MRT) (Legendre and Birks, 2012a; Simpson and Birks, 2012). For palynological examples of their use, see Pelánková et al. (2008: CART) and Herzschuh and Birks (2010: MRT). In the first case using CART, modern pollen assemblages were used as predictors to evaluate how modern pollen assemblages reflect modern vegetation types, landscape types, and different climate variables. In the latter case, a multivariate regression tree (MRT) was used to identify the major modern climate thresholds for the composition of modern pollen assemblages. Other useful numerical tools in the analysis of modern or stratigraphical pollen data include (1) indicator species analysis (Legendre and Birks, 2012a) to detect indicator pollen taxa for particular groups of samples (e.g., Herzschuh and Birks, 2010), (2) multiresponse permutation procedures (MRPP) to assess statistical differences between groups of modern pollen samples collected from the same vegetation type and from different vegetation types (e.g., Herzschuh and Birks, 2010), and (3) analysis of similarity (ANOSIM) to assess the statistical significance of overall differences in modern spectra and pairwise ANOSIMs to evaluate differences in modern spectra from different vegetation types. By looking at the overall percentage contribution that each pollen type makes to the average dissimilarity between pairs of groups, one can determine the pollen types most influential in discriminating between the two groups of samples (SIMPER, similarity percentage tests). See Bhattacharya et al. (2011) for a use of ANOSIM and SIMPER with modern pollen data and Birks (2012c) for introductions to these and related techniques.

Two or More Stratigraphical Sequences

When two or more paleoecological variables (e.g., pollen, diatoms) have been studied in the same stratigraphical sequence (multiproxy studies – Birks and Birks, 2006), numerical zonations based on each set of variables and a comparison of the resulting partitions can help to identify common and unique changes in different variables, for example, pollen reflecting catchment vegetation and diatoms reflecting within-lake conditions, or pollen reflecting regional-scale vegetation and plant macrofossils reflecting local vegetation (Birks and Gordon, 1985). Separate ordinations of the different data-sets help to summarize the major patterns within each data-set, and these patterns can be compared by, for example, oscillation logs (Birks, 1987). In cases where one data-set can be regarded as representing ‘response’ variables (e.g., pollen) and another data-set can be regarded as reflecting potential ‘predictor’ or explanatory variables (e.g., stable isotope ratios; independent climate estimates), constrained ordinations (RDA, CCA, DCCA) and associated Monte Carlo permutation tests (ter Braak, 1996) can be used to assess the statistical relationship between the two data-sets. This approach is discussed further under Data Interpretation.

Comparison of two or more pollen-stratigraphical sequences can be undertaken by ordinating the data from all sequences together by unconstrained PCA, CA, or DCA or by constrained RDA, CCA, or DCCA using site identity coded as nominal 1/0 (‘dummy’ variable) constraints. Sequence-slotting with or without external constraints (e.g., tephra layers) can provide a direct comparison of sequences and can, if an absolute chronology is available, assist in the construction of time–space correlation diagrams (Birks and Gordon, 1985; Thompson et al., 2012).

Differences between sequences are more difficult to characterize and display. Difference diagrams (Birks, 2012b; Birks and Gordon, 1985) where the differences in pollen composition at the same time between two sites, each with a reliable chronology, are calculated and displayed, can be useful tools for summarizing differences between sites at, for example, different altitudes or on different soil types.

Two or More Geographical Data-Sets

Patterns in two or more spatial data-sets (e.g., modern pollen assemblages and pollen assemblages prior to European settlement in North America) can be compared by separate ordinations or clusterings of the two data-sets and the mapping of the sample scores or group memberships for different times. Difference maps, where the values of a pollen type for time $t - 1$ are subtracted from the values of the same taxon for time t , can be constructed to highlight geographical patterns of increase or decrease in particular pollen taxa (Birks and Gordon, 1985).

Through a careful and critical use of appropriate numerical procedures, it is possible to derive a consistent and repeatable description and summary of the major patterns of variation within and between stratigraphical and geographical palynological data-sets. Numerical methods are particularly useful for these purposes because they highlight and identify the major ‘signals’ within the data-set(s) and relegate the inherent ‘noise’ within the data to a subordinate role.

Data Analysis

Data analysis is used here to include specialized techniques that estimate particular numerical characteristics from pollen-stratigraphical data. Examples include palynological richness, modeling of population changes and growth rates, rates of change, periodicities and power spectra, and inferred past environment.

Palynological Richness

Rarefaction analysis (Birks and Line, 1992) estimates the palynological richness within and between sequences. It estimates how many taxa would have been found if all the pollen counts had been the same size. The actual minimum count among the sequence(s) of interest is usually used as the base value. The interpretation of palynological richness as a record of past biodiversity is complex and currently unresolved (Odgaard, 1994, 1999; van der Knaap, 2009). In an integrated palynological, socioeconomical, and land use historical study, Hanley et al. (2008) showed that recent changes in palynological richness in several sites in the Scottish uplands were best predicted, in a statistical sense, by livestock prices, a proxy for grazing pressure.

Population Analysis

Stratigraphical PAR can be viewed as temporal records of past plant populations within the pollen source area of the study site. Sequence-splitting (Birks, 2012b; Birks and Gordon, 1985) divides the PAR of individual taxa into units of presence or absence, and when the taxon is present, into units of uniform mean and variance. It focuses on the individualistic behavior of taxa and on similarities and differences in the patterns of change of taxa within one or more sequences (Birks and Gordon, 1985). Sequence-splitting is one type of classification tree where depth is the sole external predictor (Birks, 2012b). PAR of individual taxa can also be modeled using logistic or exponential population growth models and population doubling times can be estimated for individual taxa as a means of comparing population rates of change between taxa, sites, and geographical regions (Birks and Gordon, 1985).

These types of models are *a posteriori* modeling (*sensu* Flenley, 2003) where pollen-analytical data are used and mathematical population models are then fitted to aid data analysis. The models fitted can be relatively complex, such as nonlinear population models (e.g., Jeffers et al., 2011, 2012) that allow testing of alternative hypotheses about potential drivers of change. Their use thus lies between data analysis and data interpretation.

In the alternative *a priori* approach to modeling (Flenley, 2003), a landscape vegetation dynamics or forest succession model is used (e.g., Heiri et al., 2006). These models require parameters for each taxon (e.g., longevity, seed productivity, growth rate, etc.) and independently derived climate estimates to 'drive' the model. The model attempts to simulate what may have happened in terms of vegetation composition and taxon abundance at a given spatial scale, and the simulation results

can be compared with actual pollen-analytical data. These models are used to test ecological hypotheses about, for example, drivers of long-term treeline or forest limit changes (Heiri et al., 2006).

Rate-of-Change Analysis

Rate-of-change analysis (Grimm, 1988; Grimm and Jacobson, 1992) estimates the amount of palynological compositional change per unit time in stratigraphical data. It is estimated by calculating the multivariate dissimilarity (e.g., chord distance) between stratigraphically adjacent samples and by dividing the dissimilarity by the estimated age interval between the sample pairs. An alternative approach is to interpolate the data to constant time intervals, calculate the dissimilarity, and divide by a constant time interval. The data can, if required, be smoothed prior to interpolation (Birks, 1998, 2012b). Rate-of-change analysis is critically dependent on a reliable chronology for the sequence. Because radiocarbon years do not always equal calendar years (Blaauw and Heegaard, 2012) (see *Calibration of the ¹⁴C Record*), a carefully calibrated timescale or an independent absolute chronology (e.g., from laminated sediments) are essential for reliable rate-of-change estimation (Birks, 1998).

Time Series Analysis

Pollen-stratigraphical data represent time series of the changing frequencies or accumulation rates of different pollen types through time. There are two main approaches to time series analysis. There is the time domain approach that is based on the concept of autocorrelation, namely, the correlation between samples in the same sequence that are k time intervals apart. The autocorrelation coefficient is a measure of similarity between samples separated by different time intervals, and it can be plotted as a correlogram to assess the behavior (e.g., periodicities) of the pollen type of interest over time. Time series of two different variables can be compared by the cross correlation coefficient to detect patterns of temporal variation and relationships between variables (e.g., Tinner et al., 1999).

The second approach involves the frequency domain and focuses on bands of frequency or wavelength over which the variance of a time series is concentrated. It estimates the proportion of the variance that can be attributed to each of a continuous range of frequencies. The power spectrum of a time series can help detect periodicities within the data and the main tools are spectral density functions, cross-spectral functions, and the periodogram. Recent palynological examples include Willis et al. (1999) and paleolimnological examples are reviewed by Dutilleul et al. (2012) and Cumming et al. (2012).

Conventional time series analysis makes stringent assumptions of the data, namely, that the intersample intervals are constant and that the data are stationary, and thus, there are no trends in mean or variance in the time series (Dutilleul et al., 2012). In the absence of equally spaced samples, the usual procedure is to interpolate samples to equal time intervals. This is equivalent to a low-pass filter and may result in an underestimation of the high-frequency component in the spectrum. Techniques have recently been developed for spectral

and cross-spectral analysis for unevenly spaced time series, so-called temporal series (Dutilleul et al., 2012), but they do not appear to have been applied to pollen-stratigraphical data, although they have proved useful in analyzing paleolimnological temporal series (Cumming et al., 2012; Dutilleul et al., 2012).

A limitation of all power-spectral analyses is that they provide an integrated estimate of variance for the entire time series. This can be overcome by wavelet power-spectral analysis that identifies the dominant frequencies in different variables and displays how these frequencies have varied through the time series. Brown et al. (2005) show the value of wavelet analysis in the analysis of palynological data and Birks (2012d) outlines paleolimnological and paleoclimatological uses of wavelet analysis for unevenly sampled time series.

Pollen-Based Climate Reconstructions

Since the pioneering work by H.S. Cole and T. Webb III in the quantitative reconstruction of past climate from pollen-stratigraphical data, several approaches have been developed to derive so-called modern 'transfer' or calibration functions that model the relationship between modern pollen assemblages and modern climate. These calibration functions are then used to transform fossil pollen assemblages into estimates of past climate. The various approaches are reviewed by Birks (1995) and Birks et al. (2010) and the problems and pitfalls in pollen-based climate reconstructions in Europe are discussed by Birks and Seppä (2004).

The approaches to quantitative reconstruction of past climate from palynological data fall into three main types (Birks et al., 2010): the indicator species approach, the assemblage approach (e.g., modern analog-based techniques including response surface analysis), and the calibration function or multivariate indicator species approach involving some form of linear or nonlinear regression and calibration (e.g., segmented inverse linear regression, principal components regression, two-way weighted averaging, weighted averaging partial least squares regression). Because each numerical procedure has its own biases, careful model selection using split-sampling cross validation is essential (Birks, 1995; Juggins and Birks, 2012). When several models appear equally appropriate, a consensus reconstruction can be derived by fitting a robust smoother (e.g., a LOWESS (locally weighted least squares) smoother) through the reconstructed values derived from different models (Juggins and Birks, 2012).

A major development is the development of a robust statistical procedure to test if a quantitative reconstruction inferred from fossil pollen assemblages explains more of the variation in the fossil assemblages than reconstructions based on randomly derived climate variables (Telford and Birks, 2011). Reconstructions that fail this basic test of statistical significance thus have limited credibility and should only be interpreted with extreme caution.

A hidden problem in the use of modern pollen-climate calibration functions is spatial autocorrelation, an inherent property of all spatially distributed data. The estimation of the predictive power of any calibration function assumes that the test sets used in cross validation are independent of the sites used in the calibration function (Telford and Birks, 2005).

Cross validation in the presence of spatial autocorrelation violates this assumption. Telford and Birks (2009) have developed methods for detecting and describing spatial autocorrelation, quantifying its effects, testing the significance of a calibration function in autocorrelated environments, and implementing cross validation that is robust to autocorrelation. Some pollen-climate calibration functions have no predictive power because of the strong impact of spatial autocorrelation (Telford and Birks, 2009).

Given these recent statistical developments and an increasing concern about the ecological and paleoecological assumptions in the use of calibration functions (Birks et al., 2010; Juggins and Birks, 2012), the use of such calibration functions for quantitative environmental reconstructions requires care and critical awareness and understanding of the assumptions, strengths and weaknesses, and numerical problems in calibration functions (see Juggins and Birks, 2012).

Similar approaches using calibration functions or modern analog techniques (MATs) and modern pollen and satellite-based images can be used to reconstruct conifer or deciduous forest cover, total vegetation cover, or leaf area index from fossil pollen assemblages over broad areas (e.g., Tarasov et al., 2007; Williams, 2002; Williams et al., 2011).

Data Interpretation

Pollen-stratigraphical data are a complex reflection of the vegetational composition around the study site. Interpretation of these data can be in terms of past vegetation or in terms of possible factors that have influenced changes in vegetation and hence in pollen stratigraphy (Bennett and Willis, 2001).

Vegetation Reconstruction

The reconstruction of past vegetation can be attempted using modern pollen representation factors and models of pollen deposition (e.g., Soepboer et al., 2010), finding pollen of indicator species characteristic of particular vegetation types today (e.g., Herzschuh and Birks, 2010), or comparing quantitatively fossil pollen assemblages with modern pollen assemblages from known vegetation types today, the so-called MAT. The basic idea of the MAT is simple – compare the fossil assemblage with all modern pollen assemblages using an appropriate dissimilarity measure (e.g., chord distance), find the modern assemblage(s) most similar to the fossil assemblage, assign the modern vegetation type(s) of the closest analog(s) to the fossil assemblage, and repeat for all fossil assemblages (Simpson, 2007, 2012). Problems arise in defining a critical threshold to decide if the modern and fossil assemblages are sufficiently similar to indicate that they could be derived from the same vegetation type. Fossil assemblages may, for a variety of reasons, have no close modern analog (Jackson and Williams, 2004). In such cases, the MAT will fail as a tool for interpreting fossil assemblages in terms of past vegetation. Attempts have been made to put the MAT on a more rigorous numerical basis (Simpson, 2007, 2012) using receiver operating characteristic analysis, logistic regression, and Monte Carlo simulation. The robustness of these approaches remains to be

assessed with different data-sets and in different geographical areas (Simpson, 2007, 2012).

An alternative but less formal approach to analog analysis is to ordinate or cluster together the modern and stratigraphical data (Birks and Gordon, 1985) and to examine what modern and fossil samples are positioned near each other or are clustered together. Alternatively, the modern pollen data can be ordinated (e.g., using PCA, CA, or DCA) and the modern vegetation type displayed on the ordination plots of the first few ordination axes. The fossil samples can be positioned as ‘passive’ or ‘supplementary’ objects into the plane formed by the modern ordination axes. Alternatively, fossil samples can be the basis of the primary ordination and modern samples added as ‘supplementary’ objects. A more formal approach involves multiple discriminant analysis (canonical variate analysis). It can be used to display the maximum between-group variance relative to the within-group variance of modern samples from known vegetation types. Fossil samples from unknown vegetation types are then assigned (‘identified’) to one of these modern vegetation types (Birks and Gordon, 1985).

Causative Factors

Many factors can influence the composition of vegetation and hence the composition of pollen assemblages – soil changes, climatic changes, human impact, pathogens, species interactions, disturbance regimes, lags in migration and population expansion, and complex interactions between these factors (Bennett and Willis, 2001). It is a major challenge to test competing hypotheses about underlying causative factors. Statistical techniques such as constrained ordination (e.g., RDA=reduced-rank multivariate regression, CCA, DCCA) and associated Monte Carlo permutation tests can be used to assess the statistical relationships between pollen data (‘responses’) and external forcing factors (‘predictors’), for example, to assess the relative impacts of climatic change and volcanic tephra deposition on pollen assemblages and hence on past vegetation (Lotter and Birks, 1993) or the role of fire on vegetation dynamics (Feurdean et al., 2009). Although statistical techniques exist with permutation tests that can take specific account of the time-ordered nature of pollen-stratigraphical data, the major problem is deriving, for statistical analysis, data that reflect potential forcing factors (Lotter and

Birks, 2003). This remains a major challenge in the interpretation of all Quaternary pollen-analytical data – see Lotter and Birks (1993, 2003), Mitchell (2004), and Jeffers et al. (2011, 2012) for examples of different approaches to hypothesis testing in Quaternary pollen analysis.

Software and Computing

Some numerical methods require the use of software to implement them, and new and important numerical methods relevant to Quaternary palynological data analysis are constantly being developed by applied statisticians and quantitative paleoecologists. The rate of development of new methods greatly exceeds the production of user-friendly dedicated software such as TILIA, C2, or PSIMPOLL. Virtually all the new methods are available as packages and scripts for public use free of charge within the R software development package and environment (www.r-project.org) (Table 3). Given the wide array of freely available R packages (e.g., vegan, rioja, analogue, paleoSig) and scripts relevant to pollen analysts and the ever-increasing power of personal computers, there is no excuse for palynologists to use outdated, suboptimal numerical techniques in the analysis of their hard-earned data. There is inevitably a steep learning curve in the initial stages of using R, just as there is in any other programming environment (e.g., GenStat, MATLAB), but the final rewards are well worth the initial effort. Using R and new specially developed techniques is a challenge for the Quaternary palynological community now and in the immediate future.

There are also many books available now that provide excellent introductions to the use of R in the numerical and statistical analysis of data – see Table 4.

Future Developments

Considerable advances have been made in the numerical analysis of Quaternary palynological data since the pioneering attempts in the late 1960s and early 1970s, particularly in the descriptive and narrative phases of pollen-analytical studies. In the descriptive phase, basic patterns are detected, assessed, described, and classified, and the relevant numerical

techniques are all part of this phase. The various approaches to data analysis discussed above contribute to the narrative phase where plausible, inductively based explanations, generalizations, and reconstructions are derived from the observed patterns. Hypothesis-testing techniques such as RDA, CCA, DCCA, and associated permutation tests are one approach to the analytical phase in science where falsifiable or testable hypotheses are proposed, evaluated, tested, and rejected.

More work is needed to improve and to quantify comparisons and interpretations of stratigraphical data and to test competing hypotheses about possible causative factors in influencing past vegetation and hence fossil pollen assemblages at different spatial and temporal scales. Multidisciplinary paleoecological investigations are resulting in major advances because a multiproxy approach can help to test competing hypotheses (Birks and Birks, 2006; Bradshaw et al., 2005; Lotter and Birks, 2003). However, the rigorous numerical analysis of multiproxy data is still in its infancy.

A potentially important new approach to the interpretation of pollen-stratigraphical data is to use life history and other ecological traits and to link these traits to past environmental conditions through the fossil pollen record (Lacourse, 2009). Special numerical techniques that can simultaneously link paleoenvironmental data (*R*) and plant species traits (*Q*) by means of fossil pollen data (*L*), (RLQ analysis: Dolédec et al., 1996) are required for this type of analysis. Fourth-corner analysis (Dray and Legendre, 2008) is also useful for quantifying and testing the relationships between *R* and *L*. See Lacourse

(2009) for an example of these analyses to demonstrate that climate is the ultimate control on Holocene forest composition and species abundance but long-term community assembly is also constrained through interspecific differences in plant traits.

The numerical analysis of huge data-sets now available from several publicly available databases (Brewer et al., 2012) represents a major challenge because such data-sets have important spatial and stratigraphical properties (Mitchell, 2011) (see [Databases and Their Application](#)). New numerical data-mining techniques that can take account of the geographical and temporal properties of the data are required to help analyze the data (Hastie et al., 2011). Such techniques can be used to answer questions concerning common and unique trends in pollen data at a range of spatial scales, the importance of spatial and temporal autocorrelation at a range of spatial and temporal scales, and the role of causative factors at these different scales. Statistical-learning techniques such as CART, boosted trees, and random forests (Simpson and Birks, 2012) are potentially powerful techniques for analyzing huge pollen-stratigraphical data-sets. A major problem inherent in all databases is data quality (Brewer et al., 2012). The recognition of this problem is leading to new initiatives in data screening (e.g., Gonzales et al., 2009; Whitmore et al., 2005) and in assessing and reducing temporal uncertainties (Blois et al., 2011).

It is now 40 years since the pioneering work on the numerical analysis of pollen-stratigraphical data. The next 40 promises to be equally exciting, rewarding, and challenging.

Introduction

Palynological data from the recent geological past have been invaluable for understanding ecological dynamics at time-scales inaccessible to direct observation, including the reorganization of communities and ecosystems as species responded individually to climate change, historical influences on contemporary patterns of biodiversity, and biotic responses to climatic change, both gradual and abrupt. Understanding the dynamics of ecological systems requires ecological time series, but many ecological processes operate too slowly to be amenable to experimentation or direct observation. In addition to having ecological significance, fossil-pollen data are crucial for climate-model verification and are essential for elucidating climate–vegetation feedbacks that can amplify or mitigate climate variations.

Basic palynological research is site based, and palynologists have devoted innumerable hours to identifying and counting pollen grains from cores, sections, and excavations. These data are typically published in papers describing one or a few sites. Usually, the data are published graphically, as in a pollen diagram, often only showing a few of the identified taxa, and the actual raw data reside on the investigator's computer or in a file cabinet. These basic data are similar to museum collections, in that they are costly to replace, often irreplaceable, and their value does not diminish with time. Moreover, the raw data are the primary resource for new interpretations and analytical approaches. Also, similar to museum collections, they require cataloging and curation. Whereas physical specimens of large fossils, such as animal bones, are typically accessioned into museums, microfossils, such as pollen, are often not accessioned, and the digital data are the primary objects. Thus, the loss of pollen data is equivalent to losing valuable museum specimens.

Several pollen database cooperatives have assembled pollen data from various parts of the world and have archived these data in relational databases. These databases fulfill two critical needs: (1) they are a secure archive of invaluable paleobiological data and (2) they are essential infrastructure for paleoenvironmental research. Although data from individual sites are valuable in their own right, emergent properties can be investigated by marshalling data from geographic arrays of sites for synoptic, broad-scale ecosystem studies. Examples of such properties are continent-scale climate and vegetation reconstructions, which provide the historical context for

understanding biodiversity dynamics, including genetic diversity. Synoptic climate reconstructions are crucial for climate-model validation.

For the past 20 years, the managers of the various regional pollen databases have collaborated to deploy their data in identical database structures. Some regional pollen databases have had their data merged from the outset, as did, for example, the North American Pollen Database (NAPD), the Latin American Pollen Database (LAPD), and the Pollen Database for Siberia and the Russian Far East (PDSRFE). In recent years, additional efforts have been made to merge other regional databases into a Global Pollen Database (GPD). The logical next step has been to merge the pollen databases into an even broader paleo database containing a wide variety of fossil and related data, which will facilitate even broader studies of community and ecosystem dynamics. This objective is now being achieved with the development of the Neotoma Paleocology Database.

Database History

Ever since Lennart von Post first introduced the science of paleopalynology and the first pollen diagram in 1916 ([von Post, 1967](#)), pollen data have accumulated as slides in desk drawers, count sheets in file cabinets, and files now stored on various electronic media. With the advent of radiocarbon dating in the 1950s, it became possible to compare temporally controlled pollen diagrams across vast areas to assess species migrations and expansions and synchronous and time-transgressive events. Such comparisons require a 'database,' whether it is a pile of pollen diagrams or digital data in a relational database.

Efforts to develop pollen databases began in North America and Europe in the 1970s. H.J.B. Birks and B. Huntley assembled data from sites throughout Europe to produce their massive atlas of isopoll maps at 500-year intervals beginning 13 000 ¹⁴C year BP for 55 taxa ([Huntley and Birks, 1983](#)). For the most part, they extracted data from published pollen diagrams. However, this procedure had limitations, and Huntley was impelled to become one of the original organizers of the European Pollen Database (EPD; [Fyfe et al., 2009](#)). In North America, efforts of T. Webb III and colleagues at Brown University in the 1970s and 1980s led to the first organized pollen database as part of the Cooperative Holocene Mapping

Project (COHMAP Members, 1988; Wright et al., 1993). Although climate data-model comparison was the principal objective of the COHMAP project, the synoptic analyses of the pollen data, particularly maps showing the constantly shifting ranges of species in response to climate change, were revelatory and led to much ecological insight.

The COHMAP pollen 'database' consisted of a multiplicity of flat files with prescribed formats for data and chronologies. FORTRAN programs were written to read these files and to assemble data for particular analyses. T. Webb III managed the COHMAP pollen database at Brown University, but as the quantity of data increased, data management became increasingly cumbersome. Clearly, the data needed to be transferred to a relational database management system (RDBMS). Discussions with E.C. Grimm, who was based in a museum with a mission of data preservation, led to the initiation of the NAPD at the Illinois State Museum in 1990. At the same time in Europe, the International Geological Correlation Project (IGCP) 158b was conducting a major collaborative synthesis of paleoecological data, primarily of pollen, and the need for a pollen database became painfully obvious (Fyfe et al., 2009). A workshop to develop an EPD was held in Sweden in 1989, and the organizers of NAPD and EPD commenced a long-standing collaboration to develop completely compatible databases. NAPD and EPD held several joint workshops and developed the same data structure. Nevertheless, the two databases were independently established, partly because Internet and software capabilities were not yet sufficient to easily manage a merged database. The pollen databases were developed in Paradox®, which at the time was the most powerful RDBMS software readily available for the personal computer (PC) platform. NAPD and EPD established two important protocols: (1) the databases were relational and queryable and (2) they were publicly available. All data in NAPD are in the public domain. EPD contains data that are public domain as well as smaller set of restricted data that require permission from the contributor for use. In an effort to encourage public access and to diminish the number of restricted sites, the EPD Advisory Board has set a three-year limitation, after which restricted status may continue but must be reaffirmed by the contributor.

As the success of the NAPD-EPD partnership grew in terms of contributed datasets and publications utilizing the databases, working groups initiated pollen databases for other regions, including the LAPD in 1994 (Marchant et al., 2002), the PDSRFE in 1995, and the African Pollen Database (APD) in 1996. At its initial organizational workshop, LAPD opted to merge with NAPD, rather than develop a standalone database. PDSRFE also followed this model, and the combined database was called the GPD. APD developed independently, but uses the exact table structure of NAPD and EPD. Pollen database projects have also been initiated in other regions, and the GPD contains some of these data, including the Indo-Pacific Pollen Database (IPPD).

The growth of the Quaternary pollen databases has been paralleled by the development of databases for other fossil types, including the North American Plant Macrofossil Database, FAUNMAP (a database of Quaternary-Pliocene mammals from North America), the North American Non-Marine Ostracode Database, the Diatom Paleolimnology Data Cooperative, and the Strategic Environmental Archaeology

Database/Bugs Database. These databases are similar in that they essentially store lists of taxa with quantitative measurements from stratigraphic contexts, with similar metadata. All of these databases face long-term sustainability issues associated with the costs of database maintenance and development and continued data acquisition. Thus, to consolidate maintenance costs and to build a multiproxy paleo database even more useful for addressing emergent global-scale ecosystem questions than the individual databases alone, the Neotoma Paleocology Database (www.neotomadb.org) was established in 2007.

Named for the packrat, genus *Neotoma*, prodigious collectors of anything in their territories, the Neotoma database realizes the ultimate goal of a multiproxy paleodatabase with global coverage. Neotoma includes fossil data for the past 5 million years (the Pliocene, Pleistocene, and Holocene Epochs) and provides the underlying cyberinfrastructure for a variety of disciplinary database projects. Although Neotoma is a new structure, it was built on the foundation laid particularly by the GPD and FAUNMAP. Neotoma can accommodate virtually any type of fossil data. The data are accessible to anyone with an Internet connection. Neotoma database management is centralized but scientific oversight is distributed, thus providing domain scientists with quality control over their portions of the data. To this end, all data in Neotoma are stored in a single centralized database, but are conceptually organized into virtual *constituent* databases, for example, NAPD and EPD, each of which has its own governance charged with overseeing scientific issues such as taxonomy, data quality standards, data acquisition, and prioritizing tool development. Constituent database cooperatives may develop individualized and branded websites to display and distribute their portions of the database if they so desire. Constituent database projects can appoint 'data stewards' to remotely upload and update data. The primary reason for the centralized design is lower requisite IT cost for development and long-term maintenance – only one database is being maintained rather than a plethora of autonomous databases all requiring managers. Furthermore, the centralized database structure simplifies cross-disciplinary multiproxy analyses and common tool development.

The Neotoma project was initially funded by a 2-year grant from the U.S. National Science Foundation (NSF) Geoinformatics Program and was launched with a workshop at Pennsylvania State University in February 2007. The initial task was to develop a data model suitable for a wide range of paleo data, which was accomplished by merging the GPD and FAUNMAP, which represent a broad spectrum of paleo fossil data and depositional contexts, the former primarily from wet-sediment cores, the latter mainly from terrestrial excavations. Neotoma received a 5-year renewal from the NSF Geoinformatics program, which began in September 2010, when a second workshop was held in Madison, Wisconsin. The two workshops involved 50–60 participants, representing a large spectrum of paleo data, including representatives from several of the pollen database cooperatives. Other research projects utilizing Neotoma are contributing data as well.

The data from the GPD and other paleoecological databases are now available from the Neotoma website. Users can search for individual sites or datasets on a map or by several different

search criteria. Datasets can be downloaded or copied and pasted into a spreadsheet for use with other applications. In addition, the entire database can be downloaded in Microsoft SQL Server or Access format. The database and website are hosted at the Center for Environmental Informatics at Pennsylvania State University.

Neotoma currently contains data from the NAPD, EPD, LAPD, PDSRE, and IPPD. The APD is currently independent, but is slated for incorporation into Neotoma. The LAPD and Japanese Pollen Database (JPD) have also inventoried data for future incorporation into Neotoma (Figure 1).

APD and LAPD contend with much larger and less well-known floras than do the pollen databases for temperate regions. APD has made a major effort at synonymization of pollen taxa and has produced a taxonomy list, which is available from its website. Images of pollen grains are also available from the APD website. Marchant et al. (2002) have published a major compendium of the ecology and distribution of sporophyte parent-taxa in LAPD.

The pollen databases make available data published in many languages, from many countries, and from literature not always widely available. Of particular note, PDSRFE assembled data from more than 175 sites, most of which were either unpublished or published in Russian in publications not widely available outside of Russia; and they published a compendium of these sites in Russian and English, with the original reference, a short description of each site, radiocarbon dates, short interpretation, and pollen diagram (Anderson and Lozhkin, 2002).

Database Structure

Neotoma consists of a large number of tables and fields for data and metadata. Central tables to the database are (Figure 2)

- **Sites:** Name and location of site.
- **Collection units:** Typically cores, sections, or excavation units. Sites may have multiple collection units, which have spatial coordinates.
- **Analysis units:** Individual units analyzed, typically identified by depth and thickness within a collection unit. Collection units may have multiple analysis units.
- **Samples:** A data type tabulated from an analysis unit, for example, a pollen sample, a plant macrofossil sample. An analysis unit may have multiple samples.
- **Datasets:** Samples of a particular data type from a collection unit comprise a dataset, for example, a pollen dataset. A collection unit may have multiple datasets (e.g., pollen, plant macrofossils, ostracodes), and a dataset may have multiple samples of the same data type.
- **Variables:** A variable consists of a taxon, element, and measurement unit. For plants, the element is the plant organ, for example, pollen, spore, seed, needle. Thus, *Picea* pollen and *Picea* needles are different variables. For pollen, possible measurement units are number of identified specimens, percent, or present/absent. Lookup tables exist for taxon names, element types, and measurement units.

Figure 1 Pollen sites (cores and sections). Red dots – Neotoma Paleocology Database, blue dots – African Pollen Database, yellow dots – inventoried sites for inclusion.

Figure 2 Central tables in the Neotoma Paleoecology Database. Table names are in the gray boxes. Red fields are primary keys; blue fields are foreign keys; violet fields are compound primary keys. Relationships shown by connection lines. IGSN, International geo sample number.

In addition, tables exist for:

- *Contacts*: principal investigators, collectors, analysts, data contributors;
- *Geochronology*: radiocarbon and other radiometric dates;
- *Chronologies*: chronology controls (e.g., calibrated ^{14}C ages, tephras, biostratigraphic ages), age models (algorithms for assigning sample ages based on chronology controls), and ages assigned to individual samples;
- *Lithology*: core or section descriptions;
- *Publications*: bibliographic references for data and metadata;
- *Synonymy*: accepted names and synonyms, original identifications.

Quality Control

The database cooperatives make every effort to ensure data accuracy. Quality control is maintained by having data stewards with palynological training enter data and by a software interface, currently under development, between the data input files and the database files. This interface checks for many kinds of common errors and inconsistencies. Probably, the thorniest quality control issues have been nomenclature and taxonomic synonymization. On a basic level, misspellings are corrected, but, in addition, the database does synonymize some names. The database coordinators must be cognizant of taxonomic resolution. Although some datasets may not contain the taxonomic resolution of others, they may nevertheless be suitable for synoptic studies. Whereas the quality of the data is ultimately the responsibility of the contributor, checking the appropriateness of any dataset is the responsibility of the user.

Taxonomy and Nomenclature

A protocol of the pollen databases is that contributors' names for pollen types are not changed in their meaning. Thus, a taxonomic identification is not questioned; although, of course, the database coordinators may choose not to include datasets with obvious misidentifications. However, some correction and synonymization is desirable and necessary to make the database more functional. Plant taxonomy of higher plants

is largely based on the diploid sporophyte generation, and taxonomic synonymization for pollen involves complications in addition to the usual issues of nomenclatural synonymy. An important problem arises from the fact that sporophyte names are used for pollen types, but pollen types may derive from more than one sporophyte taxon. As a consequence, names are combined, many pollen types have the suffix-type appended to them, and the usage of *cf.* to indicate uncertainty is common.

Taxonomic Hierarchy

The pollen database contains a flexible taxonomic hierarchy, which stores the maximum taxonomic precision made by the analyst but allows users to aggregate taxa into higher level categories. Whereas high taxonomic precision might be desirable for certain ecological studies, lumping is necessary for synoptic studies. The essence of the hierarchy is that each pollen variable has a field that points to the next higher variable in the hierarchy. For example, *Fraxinus nigra* points to *Fraxinus nigra*-type, which points to *Fraxinus*. The hierarchy then facilitates the retrieval of all instances of *Fraxinus* pollen. Changing botanical definitions and taxonomic synonymies are a persistent problem for databases of species occurrences.

Synonymy and Naming Conventions

Three general types of synonymy exist: nomenclatural, syntactic, and pollen morphological. The database synonymizes for nomenclature and syntax, but not for morphology. Nomenclatural synonymy refers to botanical nomenclature. The regional pollen databases follow major works relevant for their area, such as *Flora of North America* (Flora of North America Editorial Committee, 1993 et seq.), *Flora Europae* (Tutin et al., 1964–1993, 1993), *Vascular Plants of Russia and Adjacent States* (Czerepanov, 1995), *Énumération des plantes à fleurs d'Afrique tropicale* (Lebrun and Stork, 1991–1997), and the *Australian Plant Name Index* (Chapman, 1991). Inevitably, with a global database such as Neotoma, nomenclatural differences occasionally occur. In general, the newer authority will be followed, or if one name varies from recommendations of the *International Code of Botanical Nomenclature* (2006), then the name

following the Code will be used. Thus, for example, families with the 'aceae' endings such as Poaceae and Asteraceae are preferred over Gramineae and Compositae.

In Neotoma, Angiosperm family names and higher ranks follow the phylogenetic classification of the Angiosperm Phylogeny Group (APG; [Angiosperm Phylogeny Group, 2003, 2009; Stevens, 2001 et seq.](#)). Some of the APG revisions based on phylogenetics change long-standing taxonomic classifications, but are consistent with pollen morphology. For example, the genus *Celtis* has been moved from the Ulmaceae to the Cannabaceae. The scabrate, triporate pollen grains of *Celtis* are more consistent with the Cannabaceae than with the rugulate, stephanoporate pollen grains of *Ulmus* and other genera remaining in the Ulmaceae. Pollen from the traditional families Chenopodiaceae and Amaranthaceae are commonly grouped together as Chenopodiaceae/Amaranthaceae (or often informally as 'ChenoAms'). Conveniently from the

palynological standpoint, APG has synonymized Chenopodiaceae with Amaranthaceae, thus the Chenopodiaceae/Amaranthaceae simply becomes Amaranthaceae (as does the former superfamily Chenopodiineae).

Nomenclatural synonymization should not change the range of pollen morphotypes intended by the original analyst. For example, APG has synonymized the Agavaceae with the Asparagaceae, a family that includes many more taxa than the former Agavaceae. However, the genera of the former Agavaceae now comprise the subfamily Agavoideae, and the name is thus changed to Asparagaceae subf. Agavoideae. Neotoma has tables for synonyms and for original identifications. Thus, an original identification of Agavaceae can be retained. In this example, the circumscription of potential taxa has not changed. However, synonymization that involves splitting or lumping potentially does change the circumscription of morphotypes included in the analyst's original identification. For example, an

Figure 3 Representations of late Pleistocene and modern plant associations as biomes (top row) and as multitaxon isopoll maps (rows 2–4). Numbers indicate cal year BP. Biomes are: CDEC, cold deciduous forest; TAIG, Taiga; CCON, cool conifer forest; CLMX, cool mixed forest; TDEC, temperate deciduous forest; WMMX, warm mixed forest; MXPA, mixed parkland; SPPA, spruce parkland; CWOD, conifer woodland; STEP, steppe; TUND, tundra. Three taxa are mapped in each multitaxon map, with a single isopoll shown for each plant taxon. Primary colors (red, blue, cyan) indicate regions where only one of the three taxa is present in appreciable numbers. Secondary colors (orange, purple, green) denote associations between pairs of taxa. Beige indicates where all three taxa overlap. Scientific names: spruce, *Picea*; sedge, *Cyperaceae*; birch, *Betula*; ash, *Fraxinus*; hornbeam, *Ostrya/Carpinus*; elm, *Ulmus*; larch, *Larix*; fir, *Abies*; pine, *Pinus*. Reproduced from [Williams JW, Shuman BN, and Webb III T \(2001\)](#) Dissimilarity analyses of late-Quaternary vegetation and climate in eastern North America. *Ecology* 82: 3346–3362, with permission.

identification of Cannabaceae prior to APG would have included the genera *Cannabis* and *Humulus*, but probably not *Celtis*. Thus, in Neotoma these earlier identifications of Cannabaceae have been changed to Cannabaceae *sensu stricto*.

Syntax refers to elements of pollen-type names that are not parts of the Linnean system (i.e., species, genus, family...). Neotoma has a set of rules for pollen syntax; for example, for types the convention is name-type with a hyphen, for example, *Ambrosia*-type, not *Ambrosia* type. For a global database, types are a problem because they often are not precisely defined, or they are defined differently in different regions. Researchers need to be aware of these issues of taxonomic precision when utilizing the database.

Pollen types with different names may be morphologically identical, but the GPD does not attempt to synonymize these for several reasons. The principal reason is that, unlike floras for the sporophyte life-history stage, complete palynological floras and monographs do not exist. The database coordinators, although experienced palynologists, have no published authority on which to base their morphological naming conventions, nor do they have the expertise to determine the full realm of morphological synonyms. They could possibly reject fine morphological distinctions that, in fact, a given palynologist has made with confidence. Although, the GPD does not synonymize based on morphology, some regional pollen databases that contribute to the GPD may synonymize based on intimate knowledge of the palynology of their region. Another important argument against morphological synonymization is that the pollen-type name may indicate the most probable derivative sporophyte taxon based on biogeographic or ecological considerations.

One other database protocol that produces name changes is that, for any dataset, pollen-type names must be mutually exclusive, which is necessary for lumping algorithms to work properly. For example, if a dataset includes *Potentilla* and Rosaceae, the latter is changed to Rosaceae undiff., because Rosaceae includes *Potentilla*. Some of these names can be somewhat cumbersome. For example, many contributed datasets include *Artemisia* and Asteroideae (or the obsolete Tubuliflorae). The latter is changed to Asteraceae subf. Asteroideae undiff.

Database Applications

The pollen databases have been widely used. Applications range from seeking to place a new record into a regional context (e.g., Nelson and Hu, 2008; Schauffler and Jacobson, 2002) to synoptic mapping at continental to global scale (e.g., Allen et al., 2010) and paleoclimatic reconstructions for evaluation of global climate models (e.g., Bartlein et al., 2011). Applications range from evolutionary biology and macroecology (e.g., DiMichele et al., 2004; Giesecke and Bennett, 2004; Petit et al., 2004) to natural resource management (e.g., Cole et al., 1998; Heard and Valente, 2009). Given the diversity of studies utilizing the pollen database, selection of a few representative examples is difficult. Nonetheless, the following two illustrate some of the more powerful synoptic applications.

Biomization is a particularly powerful technique for deriving biomes from pollen assemblages. Rather than using actual species, biomization utilizes plant functional types (PFTs),

which are based on life form, physiology, phenology, leaf form, and climatic tolerances. The method entails assigning PFTs to biomes globally, assigning pollen taxa to PFTs regionally, and using these assignments to assign regional pollen taxa to biomes. For fossil samples, 'affinity scores' are calculated between pollen samples and biomes. The biome with the highest affinity score is assigned to the fossil-pollen sample, subject to a tie-breaking rule (Prentice et al., 1992, 1996; Williams et al., 1998, 2000, 2001). Advantages of biomization are that nonanalog biomes are definable and that no reliance is placed on comparison with modern samples, which may be biased by anthropogenic activities. Williams et al. (2001) mapped biomes and major taxa for the Late Glacial interval (17 000–12 000 cal year BP) in eastern North America (Figure 3). Mapped are two nonanalog biomes – mixed parkland and spruce parkland – that no longer exist. The maps clearly show the changing biomes and taxon distributions through time. This study also showed that the peak interval of dissimilarity from the present preceded the time of maximum climate change. Thus, nonanalog vegetation does not appear to be a nonequilibrium transient state, but, in fact, is in equilibrium with nonanalog climate conditions.

Maps of fossil-pollen data show species migrations from glacial ranges or 'refugia' to their modern ranges. Modern genetic data also contain clues to the past migration history of taxa. In Europe, collaboration between palynologists and geneticists has produced a detailed history of the migration of deciduous *Quercus* from glacial refugia (Brewer et al., 2002; Petit et al., 2002). Because of frequent introgression, the various *Quercus* species share chloroplast DNA (cpDNA) haplotypes regionally, and haplotype lineages cross species lines. Consequently, the taxonomic resolution of the cpDNA lineages is comparable to the identification of pollen to the genus level. Palynological data (Figure 4) and the geographic distribution of haplotypes (Figure 5) show the existence of refugia

Figure 4 Isopoll map showing time of first arrival of deciduous *Quercus*. Adapted from Brewer S, Cheddadi R, de Beaulieu J-L, Reille M, and Data contributors (2002) The spread of deciduous *Quercus* throughout Europe since the last glacial period. *Forest Ecology and Management* 156: 27–48.

Figure 5 Maps showing inferred postglacial colonization routes for frequent cpDNA haplotypes of deciduous *Quercus*. Colors indicate different lineages, and numbers indicate haplotypes. Maps (a), (b), and (c) show different haplotypes moving from the same refugia. Gray shading indicates altitude. Reproduced from Petit RJ, Brewer S, Bordács S, et al. (2002) Identification of refugia and post-glacial colonisation routes of European white oaks based on chloroplast DNA and fossil pollen evidence. *Forest Ecology and Management* 156: 49–74.

in the Iberian Peninsula, Apennine Peninsula, and Balkan Peninsula; and isopoll maps and the distributions of haplotypes show migration routes north from these southern peninsulas to northern Europe and into central Asia. Pollen and genetic data are in agreement about general migration trends. Synoptic mapping of *Quercus* pollen shows where refugia were and when migrations occurred. Genetic survey adds detail to

the migration history; for example, DNA data show that *Quercus* in the British Isles is related to the Iberian Peninsula populations, rather than to those from the Apennine refugium. Genetic data can also suggest where more palynological work is warranted. For example, a unique haplotype in Corsica and Sardinia suggests a refugium there, although no pollen data are available to confirm it.

Conclusions

The quantity of data in the pollen databases and the hundreds of papers that have utilized these databases demonstrate their great success. The databases are public and access is free. The databases have fostered collaboration between scientists in different disciplines and from different countries, and they are critical to global change research.

The pollen data were some of the first paleo data to be organized into a relational database structure. Many lessons concerning scientific database organization have been learned. To be successful, the database must satisfy needs and wishes of both data contributors and data consumers. Some scientists had initial reluctance to contribute data. However, willingness to participate has increased with the maturation of the database and the increasing evidence of its value as a scientific resource, combined with the broader informatics revolution. A large database effort must involve a number of data cooperatives. Unfunded data contributors will send data 'as is,' but typically they will not spend much time entering or reformatting data to fit database standards.

The incorporation of the pollen databases into the multi-proxy Neotoma Paleoeology Database attends to several long-standing needs. The common cyberinfrastructure should reduce long-term maintenance costs, enhance data preservation, and guard against data loss, while the distributed governance permits expert review and oversight for particular data types. The development of a software interface allowing data stewards from the various pollen database cooperatives to upload and manage data remotely should permit these cooperatives to focus on data entry rather than IT needs. Neotoma will facilitate new multi-proxy studies of Quaternary environments.

Pollen Surface Samples and Pollen Trapping

The Need for Surface Samples and Pollen Trapping

The pollen assemblages preserved in peat and lake sediments reflect the vegetation that existed at the time when that particular sediment was accumulating. The translation of these assemblages into actual vegetation communities, however, is complicated by the differential pollen productivity, differential pollen dispersal, and differential pollen preservation properties between taxa (see [Pollen Analysis, Principles](#)). Therefore, in order to better understand and quantify fossil pollen assemblages, it is necessary to collect present-day information about the relationship between the pollen being deposited on a lake bottom or peat surface and the vegetation that produces it. Such present-day reference material falls into two broad categories: pollen extracted from surface samples and pollen collected by means of pollen traps. The major difference between the two is that for surface samples, the time period represented by the pollen assemblage is unknown, whereas in the case of pollen traps, the time interval over which pollen is being collected can be controlled. For traps, this knowledge of the time interval allows the rate at which pollen accumulates on a known surface area to be calculated, and in consequence, each pollen taxon can be considered individually rather than in terms of its percentage presence in the whole (or a predefined) assemblage.

Modern reference pollen material has been collected for almost as long as the technique of pollen analysis has been in existence, and some of the earliest work in this field ([Aario, 1943](#)) is still useful and valid today. Collection of moss polsters or lake-surface sediment is the more common procedure and the first to be employed, whereas pollen traps have been used to collect reference material for paleoecological investigations since the 1970s ([Cundill, 1986; Tauber, 1974](#)).

Surface Samples

Surface samples can be obtained from a range of material (see [Surface Samples, Taphonomy, Representation](#)). The most common source materials are moss polsters and lake-surface sediments, because these most closely resemble the characteristics of the sites recording past environments with which their pollen assemblages will be matched. In areas where such materials are missing, however, lichens, soils, and leaf litter have been used. The latter are less desirable because of the uncertainty of pollen capture and preservation, which could lead to a selectively biased pollen assemblage. Surface samples have also been obtained from snow, but in this situation, the quantity of pollen is often too small for any reliable statistical treatment ([Hicks and Isaksson, 2005](#)) or represents an abnormal and rarely occurring event ([Hjelmroos and Franzen, 1994](#)).

Two main strategies have been employed for moss polster surface sample collection. One involves taking single samples of known surface area and predetermined depth, one for each vegetation situation ([Figure 1](#)), the other of taking ten random samples of varying size from within a designated area of the studied vegetation community and amalgamating them ([Hicks et al., 1998](#)). The strategy for sampling should be related to the specific research approach in which the samples will be used (see also the section '[Sample Collection Strategy, Accompanying Data, and Archiving](#)'). The multiple-sample record may be more appropriate in areas with high plant biodiversity (meadows or Arctic tundra) and where the data set will be used for the modern analog approach (see section '[Past Land Use and Anthropogenic Disturbance to the Vegetation](#)') whereas the single-sample method is useful in species-poor communities and where comparisons with data from pollen traps are to be made, because the same surface area can be used for both.

The length of the sampling period covered by a moss polster has been much debated ([Cundill, 1991](#)), although very few experiments have been made to actually assess this. The exceptions are the studies by [Räsänen et al. \(2004\)](#) and [Pardoe et al. \(2010\)](#), who conclude that the time period is probably around 2 years. This is important because not only does pollen production vary enormously from year to year but some species (particularly temperate trees) exhibit regionally coherent cyclicity in their flowering and seed production ([Kelly, 1994; Koenig and Knops, 1998; Ranta and Satri, 2007](#)). In vegetation situations where the dominant species are big pollen producers but one of them shows cyclicity in flowering, if a sample represents only a single year, or even 2 years, the percentage presence of each pollen type can vary enormously depending upon the year in which it is sampled ([Figure 2](#)). In such situations, therefore, the percentage records have very little meaning.

There are several types of samplers available for sampling surface sediments of lakes. The most commonly used are the Kajak and Limnos samplers ([Figure 3](#)), although the uppermost layer of a frigid finger core can also be used ([Glew et al., 2001; Kansanen et al., 1991](#)). The length of time incorporated in a lake-sediment surface sample varies with the rate of sediment accumulation in the lake in question. This may be only a few years in highly productive lakes but can be tens of years in Arctic lakes ([Prentice, 1978](#)). The surface sediment of lakes with inflow streams will contain pollen coming from the catchment area of the lake, whereas the surface sediment of a lake with no inflow will contain predominantly pollen from the air and from plants growing in the lake itself and along its shores. It is potentially possible to obtain an annual sample from varved lakes (see [Varved Lake Sediments](#)), if they can be sampled varve by varve, but even so the pollen within a single varve could be a mixture of pollen produced in different years

Figure 1 Sampling a moss polster as a single (nonamalgamated) surface sample of known surface area. The moss is cut off at the ground surface, but all mineral material is excluded.

because of the mechanisms of sedimentation (Davis, 1973; Davis et al., 1971).

As a general rule, moss polster samples should be used as reference material for interpreting pollen assemblages extracted from peat, whereas samples of surface sediments of lakes are best as a reference for pollen assemblages from lake-sediment profiles. For some specific research questions, however (see Table 1), results from one type of source material are applied to the other.

One distinct advantage that surface samples have over pollen traps is that a large number of samples with a good spatial coverage can be collected during one field season, whereas, for usable data, pollen monitoring with pollen traps has to be continued for at least 5 years, and this often sets a limit on the number of pollen traps that is feasible to maintain.

Pollen Trapping

The most commonly used pollen trap in Quaternary studies is the Tauber-type trap (Hicks and Hyvärinen, 1986; Tauber, 1974). This trap, named after the Danish physicist who developed it in order to investigate pollen dispersal, is (in a slightly modified form) now the standard trap used by the pollen monitoring program (PMP; Hicks et al., 2001; Giesecke et al., 2010), a network uniting scientists interested in pollen monitoring. Other major trap types include the Cundill trap (Cundill, 1986), the Burkard sampler (Hirst, 1952), and Cour filters (Cour, 1974). The latter two are used primarily for aerobiological studies, which monitor the pollen content of the air and so will not be considered here. The Cundill trap is applicable for Quaternary studies and is preferred to the Tauber-type trap in situations where the yearly rainfall is extremely high and the vegetation is very dense, that is, in the tropics (Gosling et al., 2003).

The Tauber-type trap is usually sunk into the ground surface so that its sloping collar top with the 5-cm-diameter central opening is at ground level (Figure 4). However, depending on the research question, the Tauber-type traps can be installed at many other positions, such as on a floating raft, on a pole, or on a roof-top (Giesecke and Fontana, 2008; Levetin et al., 2000; Solomon and Silkworth, 1986).

(a)

(b)

Figure 2 Annual pollen quantities that have accumulated on a known area of land surface (the same results as in Figure 5), expressed as a percentage of the terrestrial pollen sum: (a) year-by-year and (b) averages of two consecutive years. Note the wide range in percentage values over the sampling period for the two major tree types, even though the monitoring site has always been in the same place and the surrounding vegetation has remained constant. In this example, *Picea* is not present in the local vegetation.

Ideally, monitoring locations are in the center of small (ca. 200 m diameter) mires so that the situation resembles, as closely as possible, the fossil one with which results will be compared. In forested situations, it is desirable that, if a mire is not available, the trap is placed within an opening in the forest, unless the results are to be used to interpret fossil assemblages

from small forest hollows. In temperate areas, the trap remains in position throughout the year, from the end of one growing season to the end of next one, the contents being collected at the end of the growing season. In tropical areas, without the dormant season, the span of monitoring time may be specific to other annual cycles. In this way, the temporal resolution of the results is one full year (the best resolution that is feasible

to obtain from peat or lake sediments) and includes all pollen coming to the ground surface, both directly from that summer's local pollen emission and also through resuspension and wind transport from sources at even considerable distances (Hicks, 2001).

The lower part of the trap, which is buried in the ground and in which the pollen is collected, can be of any size but should be large enough to contain the precipitation of the whole monitoring year. At the beginning of the monitoring season, enough glycerol is poured into the container part of the trap to cover the entire base. This is to make sure that any pollen entering the trap remains moist and is preserved. Small quantities of formalin

Figure 3 Sampling lake-surface sediment with a Limnos sampler. With this sampler, the loose uppermost sediments can be removed centimeter by centimeter.

Figure 4 A modified Tauber trap used for monitoring pollen deposition in accordance with the PMP protocol. (a) The trap in position in a *Sphagnum* (Peat moss) tussock. (b) The year's collection ready for transportation to the laboratory. Field procedure is simple and designed to prevent sample loss. The special monitoring lid is removed and placed on a new container while the container that has been in the field for the whole year is closed with a normal entire lid.

Table 1 Sampling strategy in relation to the research question for which the modern pollen data set will be used

Approach	Number and location of samples	Source material				Required vegetation data
		Moss polster	Lake-sediment surface sediment	Soil sample	Pollen trap	
Modern analogs: indicator species approach	Samples from within those vegetation communities for which an analog is required	X	X	X	X	Species list and abundance
Modern analogs: whole assemblage comparative approach	As above but with at least 30 sampling points	X	X	X		Species cover/frequency
Transfer functions: a. local/regional b. subcontinental	A comprehensive evenly spaced network of points covering the area/ regional/subcontinent in question	X	X	X		Major vegetation units. The sites should not be highly anthropogenic
Pollen productivity estimates	At least 30 sampling points randomly through the landscape	X	X	X	X	Detailed vegetation analyses centered on each sample plus regional vegetation out to tens of km (field data + air photos)
Background pollen estimates	Center of large lakes		X			Major vegetation units from satellite images
PARs, thresholds of abundance, measurements of pollen dispersal	A transect of monitoring points across the limit of the species in question or radiating at increasing distances from the species				X	Both detailed local- and coarser-scale regional analyses (field data + air photos)

Note: Although all the source materials are possible, they should be regarded as alternatives. That is, the data set should, in most instances, be all derived from one type of source material (either moss polsters or surface sediments), not a mixture between the different types of collecting sites.

and thymol are also added both to kill any animals and insects that fall into the trap and to prevent bacterial and fungal growth. To prevent contamination of the sample by small rodents, amphibians, or insects attracted to the traps by the glycerol, water or decaying animals, a piece of mesh or few metal bars can be placed somewhat below the opening of the trap (Koff, 2001). There are often practical difficulties with traps, such as vandalism by people, especially when the traps are placed in densely populated areas, or damage by large animals (e.g., bears and bovines) attracted to the glycerol, sometimes making it impossible to conduct pollen trapping at certain locations (Hall, 1990; Tonkov et al., 2001; van der Knaap et al., 2001).

Pollen traps are most easily placed on land and, therefore, produce data applicable for a terrestrial environment, although there is a growing body of evidence to suggest that the results can also be applied to interpret pollen records from lake cores provided that the lakes have no inflow streams and are of the same size as the opening in the forest in which the pollen trap was placed (Hicks and Hyvärinen, 1999). Experiments made by Giesecke and Fontana (2008) with pollen traps floating on the lake-surface to evaluate the relationship between pollen accumulating in this situation and that accumulating at the lake floor and in the terrestrial traps found no substantial differences in observed pollen deposition.

During the laboratory preparation of the pollen trap contents, marker grains are added (Stockmarr, 1971) which enable the total pollen concentration of the trap contents to be calculated. Because the pollen is collected for 1 year and the surface area of the collection opening is known, the pollen accumulation rate (PAR) in grains $\text{cm}^{-2} \text{year}^{-1}$ can then be calculated. The term 'influx' has frequently erroneously (Thompson, 1980) been used in the literature to refer to the amount of pollen $\text{cm}^{-2} \text{year}^{-1}$, but correctly this should be referred to as PAR. The precision of the PAR calculation depends on the relationship between the number of marker grains and the number of pollen grains counted in the preparation, so ideally the results should be expressed together with their confidence intervals (Maher, 1981).

Results of pollen trapping in northern Finland that have continued for more than 40 years demonstrate great annual

variation in the PAR (Figure 5; for the confidence limits on these calculations, see Hicks, 2001), to the extent that the difference in the quantity of pollen from 1 year to the next is frequently bigger than the difference in the quantity of pollen of one taxon (e.g., *Pinus* (Pine)) between different vegetation zones. This annual variation reflects regional pollen production, which is determined by weather conditions (in the north, primarily temperature) of the year before pollen emission. When the long-term average PAR is considered, however, the value reflects the density and abundance of the different taxa in the region surrounding the trap (Table 2). The results from pollen traps, therefore, differ from those from surface samples in that, through the PARs, two signals can be extracted, one of climate and one of plant abundance, depending upon the temporal resolution at which they are considered.

For both surface samples and pollen traps, all microfossils present are identified and counted. Thus, in addition to pollen and spores, coniferous stomata, charcoal (see Charred Particle Analyses), spheroidal carbonaceous particles, testate amoebae, fungal spores, and non-pollen palynomorphs are recorded. This range of microfossils enables the results to be applied to a wider range of research questions than if only pollen and spores were recorded.

Sample Collection Strategy, Accompanying Data, and Archiving

The number of surface samples/pollen traps and their location and the detail and extent of any associated vegetation analyses varies in accordance with the intended use of the data set. Although the prime aim of the results of both types of analysis is a more objective or even quantified interpretation of fossil pollen assemblages, there are numerous ways in which this can be achieved. These include:

- modern analogs, either using the indicator species approach or the whole assemblage comparative approach;
- transfer functions, either at the local/regional or subcontinental scale; and

Figure 5 Yearly PARs for the period 1982–2001 monitored at a site in northern Finland located close to the northern forest limit of Scots pine (*Pinus sylvestris*).

Table 2 Threshold PAR values for the presence and abundance of three tree species common in northernmost Fennoscandia based on the long-term average results of pollen monitoring

	Betula (<i>Birch</i>)	Pinus (<i>Pine</i>)	Picea (<i>Spruce</i>)
Not present within 10 km		<300	<15
Not present within 1 km	<600	300–500	15–25
Present but only sparsely	600–1000	500–1300	25–140
Open forest	1000–1600	1300–2500	140–200
Dense forest	>1600	>2500	>200

Note: The numerical value is affected by the size of opening in the forest in which the pollen trap is located. Such threshold values should, therefore, only be applied to fossil situations where the opening was of similar size.

Source: Reproduced from Table 1 of Hicks S and Sunnari A (2005) Adding precision to the spatial factor of vegetation reconstructed from pollen assemblages. *Plant Biosystems* 139(2): 127–134, with permission.

- using parameters derived from the modern reference samples as input for models of pollen dispersal.

The requirements and restrictions on the number and location of surface samples or pollen traps vary in accordance with these three major research methods and are summarized in Table 1.

Unlike surface samples, the whole set of which can be collected during one field season, pollen traps are a long-term commitment, and so their location has to be most carefully planned. Of particular significance is the size of the opening in which the trap is located, because this directly affects the numerical value of the PARs calculated for the individual pollen taxa. Forest openings (in effect the area which is not covered by trees) should be of a similar size if PARs are to be compared between traps. Traps placed within forest will record predominantly local pollen deposition which can be extremely abundant, while those placed in large mires, or even on the water surface of large lakes (>1 km in diameter), will collect relatively smaller quantities of pollen, but the pollen composition will reflect an average for a large regional area.

In the majority of cases, the surface sample or pollen trap data set will be of only limited use unless it is accompanied by information on the vegetation in the area where it is collected. The desirable degree of detail in the accompanying vegetation data, however, varies with the research question being addressed (Table 1). In situations where the sample covers a long time interval, it is conceivable that during the time that the pollen assemblage has accumulated the surrounding vegetation has changed, for example, a 10-year lake-surface sediment sample in an area formerly cultivated and later abandoned, or a pollen trap located in a forest area, which during the time in question is partially felled. In such situations, the surface sample will give a mismatch for the vegetation it is collected to represent. In the case of the pollen trap, however, where data are collected every year, it is possible to follow the changes in PAR brought about by the partial felling of forest, forest fire, or year-to-year variability in climate.

It is possible to archive the results of surface sample and pollen trap analyses in the form of databases. The European Pollen Database and Global Pollen Database (see Databases and Their Application) hold records of fossil pollen sequences and modern (surface) samples, although not all parts of the world are represented. The Neotoma Database includes records of fossil pollen sequences and modern (surface) samples, as well as other paleoecological data. The PMP maintains a

database of the year-by-year records from pollen traps, with data supplied by its members. The completeness of accompanying metadata (latitude, longitude, altitude, sampling medium, date of collection, name of collector, local and regional vegetation, slope and aspect) varies considerably, and so samples should be carefully selected from those in the database so as to fulfill the requirements of the research question to be addressed. Nevertheless, these databases form a valuable publically available source of information for a wide range of different vegetation situations in diverse geographical areas.

Data Applications

Vegetation History

Past vegetation can be reconstructed from surface samples in an objective manner using the modern analog whole assemblage comparative approach. The data set for this should contain samples from the whole range of vegetation communities that are thought to have existed in the past at the location of the fossil profile. A reconstruction will not be possible if the fossil pollen assemblage does not have a modern analog. Numerical ordination or classification techniques (see Numerical Analysis Methods) applied to the surface sample data set are used to separate and characterize different plant communities, which can then be identified in the fossil record (Gaillard et al., 1992). The surface and fossil pollen assemblages can also be combined and analyzed numerically and the fossil samples interpreted according to their position (in, e.g., a principal components analysis plot) relative to the surface samples (Gaillard et al., 1994; Hjelle, 1999a).

In an alternative approach, PARs calculated from pollen trapping can be used to provide threshold values for the closeness and abundance of different species relative to the monitoring site (Table 2). When applied to fossil situations, these give a much more objective picture of past treelines (see Tree-line Studies) and the migration of species (see Changing Plant Distributions and Abundances) than can be obtained from methods which have to rely on pollen percentage values (Hicks, 2001; Seppä and Hicks, 2006).

Past Land Use and Anthropogenic Disturbance to the Vegetation

A simple and frequently used method of identifying and following human interference with the vegetation

(see [Archaeological Applications](#)) is the modern analog indicator species approach. Surface samples for this method are deliberately collected from sites exhibiting the sort of land-use situation that is expected to have existed in the past and visually inspected to pinpoint those species that are uniquely associated with each type of land use. These species then become markers or indicators of that land-use type in the fossil record (Behre, 1981, 1986; Hjelle, 1997, 1999b). As with all modern analog approaches, the modern data set may be lacking in representatives of all past land-use categories. Moreover, the method assumes that the tolerance of the indicator species to the relevant environmental variables has not changed over time. The whole assemblage comparative approach mentioned above can also be applied to reconstruct past land use.

Climate Reconstructions

One common use of surface samples is in climate reconstructions, either at the broad regional scale or at the coarser global scale. A common practice is to use transfer functions in which the pollen data are translated into a climate parameter (see [Approaches, Use of Pollen as Climate Proxies](#), and [Mire and Peat Macros](#)). For this approach, the modern training set should cover the full range of variability in the climate parameter being reconstructed, which usually means obtaining a data set with a wide geographical spread and a dense spatial network (Birks and Seppä, 2004; Birks et al., 2010).

Results from pollen trapping in temperate areas are beginning to reveal that the annual variation in pollen production calibrates with temperature of the summer in the year before pollen emission (Autio and Hicks, 2004). There is the possibility, therefore, that if continuous PAR records at an annual resolution can be obtained from sediment profiles, these would provide a proxy record of summer temperature variation through time.

Models of Pollen Dispersal and Deposition

Models of pollen dispersal rely on surface sample results in order to calculate pollen productivity estimates and establish the composition of the background pollen within a given region (Sugita, 1994; Sugita et al., 1999). Moss polsters or samples of surface sediments of lakes, collected from random locations of investigation area, are most commonly used for pollen productivity estimates (Broström et al., 2008). For estimating background pollen composition, samples must be taken from the centers of large lakes (of a size larger than the relative source area of pollen for the region), because it is the consistent regional component of the pollen assemblage that is required (Hellman et al., 2008). Surface samples or data collected by means of pollen traps can be used to evaluate vegetation reconstruction model performance (Sugita et al., 2010).

Stand-Scale Palynology

R H W Bradshaw, University of Liverpool, Liverpool, UK

© 2013 Elsevier B.V. All rights reserved.

Introduction

Conventional pollen analysis records vegetational change at spatial and temporal scales that are largely unfamiliar to the plant ecologist. Forest succession, or the predictable replacement of one group of plants by another, is usually observed at the scale of the woodland stand (10^2 – 10^3 m²) during the lifetime of the ecologist, but pollen analysis of lakes and bogs reconstructs vegetation cover from far larger areas (10^4 – 10^6 m²), typically over time periods of thousands of years. Forest hollows and other ‘closed-canopy’ sites, by contrast, are dominated by pollen and spores that have traveled only a few meters from source plants and thus resolve vegetation dynamics at the scale of the woodland stand. Vegetation can be reconstructed with very high spatial resolution that can be easily compared with plot-based surveys of modern vegetation. Thus, stand-scale palynology provides a key link between paleobotanical and contemporary ecological studies. Ecological processes and properties that can be more easily studied using stand-scale rather than conventional palynology include the following: (1) the effects of disturbance on vegetation, either events such as fire, disease, or storm damage, or chronic disturbance such as animal browsing; (2) species invasions, succession and its relationship to climatic change, and anthropogenic impact; and (3) vegetation structure and openness. Stand-scale palynology is well suited to complement archaeological investigations where the study sites are often small and spatially well defined.

History

Stand-scale studies began in Scandinavia, as did many methodological developments in palynology. The approach was adopted and developed in the British Isles and former colonies and then the initiative passed to North American scientists where many of the recent developments have taken place. Iversen (1964) in Denmark was the first to fully appreciate the benefits of local-scale palynological studies even though isolated earlier studies had taken place in Norway and Sweden. Iversen realized the potential of stand-scale studies to yield specific insights into dynamic ecological processes and in 1949 established a field laboratory within the 200 ha Draved Forest, Denmark, with the aim of developing the subject. Pollen–vegetation relationships, vegetation monitoring, and pollen analysis from 30 stand-scale sites were among the ongoing studies before these unique observations and experiments were terminated due to lack of funding in 2003.

Special mention must be given to the related topic of soil palynology, which was largely developed by Dumbleby (1957, 1985). Soil palynology has developed more within archaeological than Quaternary science, yet shares some of the special features of stand-scale palynology of wetland and mor humus sites. Andersen (1970) was a landmark paper in development

of the relationship between source vegetation and stand-scale pollen deposition and the detailed history of Løvenholm Forest was a showcase for the power of the technique (Andersen, 1984). Iversen used mor humus profiles to describe the development of Draved Forest over recent millennia, while Andersen sampled forest hollows from Løvenholm Forest that covered most of the Holocene. These forests today are important reference areas for the study of undisturbed forest processes, yet the pollen studies showed how most of the forest area had been significantly altered by human activity beginning thousands of years ago. Such studies have improved our detailed understanding of the past relationships between people and vegetation in Northwest Europe.

Andersen also demonstrated a strong empirical relationship between pollen deposition at a single point on the forest floor and the present vegetation within a 20–30 m radius. This finding was supported by Bradshaw (1981) but was later modified by thorough field investigations in the 8500 ha Sylvania Wilderness, Upper Michigan, USA (Calcote, 1995; Sugita, 1994). A review of the subject was made by Bradshaw (1988), and later, Mitchell (1998) covered some further developments and showed how stand-scale studies contributed to discussion about the openness of Northwest European forest structure (Mitchell, 2005). Syntheses of case studies involving suites of stand-scale sites are the best illustration of how stand-scale palynology provides an important interface to issues within dynamic ecology (Bradshaw and Lindbladh, 2005; Bradshaw et al., 2005; Davis et al., 1998). Although forest peats are found in the tropics and subtropics, almost all of the published stand-scale sites are from glaciated regions within boreal and temperate forest areas.

Pollen Representation Theory

Andersen (1970) adopted a largely empirical approach to pollen representation at the stand-scale and developed correction factors to relate pollen counts more closely to source vegetations that have been widely adopted. He observed that within a forest, pollen seemed to land closer to its source than was predicted by physical laws describing the dispersal of small particles. He ascribed this observation to special properties of turbulent air movement under the forest canopy. Prentice (1985) developed a pollen representation theory that accounted for the special properties of stand-scale sites, and his approach laid the foundation for later models that consider pollen production and dispersal issues and allow quantitative landscape reconstruction. The POLLSCAPE model assumes that all pollen disperses through the air as single grains and this assumption is often violated at the stand scale. POLLSCAPE predicts that stand-scale sites have a somewhat larger source area for pollen (>50 m radius) than that observed by Andersen. The differences are not great, however, and there is a general consensus that stand-scale sites sample vegetation at a different scale compared

to conventional sites, which are usually chosen so as to yield a regional record. Stand-scale sites are much smaller than conventional sites and ideally are located under a closed tree canopy. Plant macrofossils, insect remains, and charcoal can also be preserved in stand-scale sites, and the basis for their interpretation is increasing as more sites are investigated. Stand-scale sites are best suited for detecting severe, infrequent fires using charcoal fragments larger than 150 μm (Higuera et al., 2005).

Types of Sites

Pollen is preserved in a variety of settings beneath forest canopies. If the forest canopy is temporarily or permanently removed, a considerably increased proportion of the pollen preserved at any one point derives from vegetation so far from that point that stand-scale resolution is effectively lost (Jacobson and Bradshaw, 1981). Suitable sample sites fall into three broad categories: small, wet, forest hollows (Figure 1); accumulations of mor humus; and soils of low biological activity (Table 1). The sediment in forest hollows may be mud or peat, and the pollen is preserved by waterlogging. Sedimentation can be continuous over thousands of years, but hiatuses are rather common, and the sites are sensitive to fluctuating water tables. Mor humus is a dry, acidic accumulation of partially decomposed plant litter of very low biological activity. This humus type is typically associated with acidic, free-draining soils such as podzols and is found under trees producing a leaf litter of high polyphenolic content. Little or

Figure 1 Small forest hollow in Suserup Skov, Denmark. Photograph by Gina Hannon.

no mixing occurs, and pollen is prevented from downwashing by becoming trapped in aggregates of humic material. Downwashing and mixing does tend to occur in soils, but where pollen concentrations are high, information about past vegetation can be extracted, for example, in soil horizons buried under archaeological monuments (Andersen, 1997).

Each type of site has its own assets and problems for the palynologist. The major asset of all these sites is their small pollen source area and hence their good spatial resolution. They can provide information about taxa that produce sparse amounts of poorly dispersed pollen such as *Arbutus unedo* (strawberry tree), *Ilex aquifolium* (European holly), and *Tilia cordata* (small-leaved lime), whose past history is hard to determine from conventional pollen sites. Frequently, high temporal resolution can be attained to match the spatial resolution, especially in mor humus.

Pollen grains from closed-canopy sites are more exposed to oxidation and microbial action than in conventional sites, posing potential preservation problems. Soil pollen samples tend to be the worst preserved, and large numbers of deteriorated grains or high values of resistant types, such as *Polypodium* (polypody fern) spores, indicate a probable preservation bias. Preservation can be excellent, and several forest hollows with plant macrofossil records have been reported (Figure 2;

Figure 2 Acorn cup of *Quercus petraea* (sessile oak) about 6000 years old recovered from a forest hollow in Suserup Skov, Denmark. Photograph by Peter Wærn-Moors.

Table 1 Properties of stand-scale, closed-canopy sites

	Small hollows	Mor humus	Soils
Length of record (years)	10 ³	10 ² –10 ³	10 ¹
Continuity of record	May be patchy	Good	Poor
Temporal resolution (years/sample)	10–100	1–10	–
Mixing or downwash of pollen	Minimal	Minimal	Yes
Pollen preservation	Usually good	Good	Poor
Macrofossils	Occasionally present	No	No
Charcoal	Present	Usually present	Usually present
Site availability	Restricted	Restricted	Widespread

Hannon et al., 2000). Macrofossils are very rare in humus or soil samples, although charcoal fragments can be found in all site types.

Insights from Case Studies

Sylvania, Upper Michigan, USA

Davis et al. (1998) used pollen analysis of forest hollows to investigate the late Holocene invasion of mixed deciduous stands by *Tsuga canadensis* (eastern hemlock) in Sylvania, Upper Michigan, USA. They asked whether the timing of the invasion was simultaneous throughout the study area and whether the invasibility of the area was affected by species composition. These are questions of importance to biologists that cannot be addressed using traditional palynological techniques. They compiled a dataset comprising ten sediment cores collected along a 10 km transect. Sediment accumulation began at different times from the Late Glacial until only 1200 years ago, but once initiated, apparently continued until the present day. They believed this was attributable to a continuously rising water table, but it does illustrate the special sensitivity of forest hollow sites to fluctuating water tables. Sediment accumulation rates were typically 1–3 cm per century with high pollen concentrations and generally good preservation (Davis et al., 1998).

Windstorms were recorded in the sediments by wood layers and sharp increases in pollen abundance of *Betula* (birch), but the invasion of eastern hemlock was not facilitated by disturbance. The vegetation has retained a patchy structure throughout the Holocene, and *Tsuga* preferentially invaded stands previously dominated by *Pinus strobus* (eastern white pine) around 3000 years ago (Figure 3 H1–H4). The invasion process took a few hundred years. Once *Tsuga* had invaded a stand, it maintained its dominance until today with a gradually increasing abundance, probably reflecting the regional increase in moisture.

Stands that today are dominated by *Acer saccharum* (sugar maple) and *Tilia grandifolia* (large-leaved lime) had multiple origins (Figure 3 M1–M4). Some were converted from *Tsuga* stands following disturbance, while others gradually lost *Quercus* (oak) during long periods of time. The spatial and numerical precision of these vegetation reconstructions is striking and quite distinct from interpretations that can be made from conventional, regional palynological studies. The 3000-year stability of most of the *Tsuga* stands is in contrast to the greater dynamics observed in the mixed hardwood stands and gives new insight into the development of patchiness in vegetation.

Southern Scandinavia

Several forest hollows have been investigated in southern Sweden and Denmark that permit analyses and insights into vegetation dynamics and drivers at a range of spatial scales. Maps of southern Sweden have been prepared that compare stand-scale composition with regional forest composition interpreted from conventional lake and peat sites (Figure 4; Lindbladh and Foster, 2010; Lindbladh et al., 2000). Deciduous forest types dominated the central and western landscapes at 1250 BC (calendar years), while *Pinus* (pine) was abundant

toward the east. Deciduous taxa such as *Alnus* (alder), birch, *Corylus* (hazel), oak, and lime were all common, but no single taxon was a clear regional dominant. *Fraxinus excelsior* (European ash) and *Ulmus* (elm) were less abundant than the other major tree taxa. The stand-scale records from 1250 BC confirm the dominant role of deciduous trees with only a single site recording abundant *Pinus*. Single taxa could dominate individual stands, but although one taxon comprised more than 50% of the basal area in four stands, it was a different taxon (alder, birch, pine, and oak) in each case. A kaleidoscope of forest stands was probably found in a diverse, deciduous forest landscape.

By AD 500 European beech had become established at the landscape scale, particularly in the southeast and western regions (Figure 4). *Pinus sylvestris* (Scots pine) maintained its importance in the east. Norway spruce was becoming a component of the northern forests, and increased importance of *Betula* and *Juniperus communis* (common juniper) in the central part of the region indicated widespread disturbance of forest cover. At the stand scale, the pie diagrams show an increasing importance of birch and pine at the expense of alder and lime. Stand-scale dominance patterns could differ from the regional abundance. For example, beech dominated a stand in the northwest in a region that only supported 2% beech, although beech was more abundant in the regional vegetation to the north.

The maps from the present forest landscape show the widespread dominance of conifers, chiefly spruce but with abundant pine, particularly in the east and southern parts of the region (Figure 4). The present-day map shows a good general agreement with recent forest inventory data, although there is rather little spruce recorded from southern parts of the boreal-temperate forest ecotone. Spruce is close to its natural southern limits here, and there has been much planting during the present century. Young, dense plantations produce little pollen in relation to forest volume, and there is also a possible temporal mismatch between the pollen and tree data. The pollen data are from bioturbated sediments and can integrate pollen input spanning 50–100 years, especially in the soft, unconsolidated surface sediments that are difficult to sample with accuracy. Birch and beech are the commonest deciduous taxa, and this pattern is also observed in the stand-scale records. Spruce, birch, and pine, the three major boreal taxa, comprise over 70% of the forest volume in 9 out of 13 stands. Three of the remaining stands are northern beech outliers, and one record is from a recently clear-felled area. Both the regional and local records show the same general tendency of declining abundance of deciduous taxa (except birch and beech) and an increasing tendency for one or two taxa to dominate both stands and landscapes. The northern beech-dominated stands, however, differ from the surrounding regional composition showing that forest hollows can detect stands that are unrepresentative of the landscape. Nevertheless, most stands broadly reflect the landscape-scale shifts in composition during the last 3250 years, although individual taxa show greater ranges of abundance in the stand-scale records.

Stand-scale compositional trends

The detrended correspondence analysis (DCA) of the calibrated pollen data from the individual forest stands for 1250 BC, AD 500, and the present, portrays the similarities

Figure 3 Trajectories through time of pollen assemblages (a) in *Tsuga* hollows and (b) in hardwood hollows projected into canonical variate analysis (CVA) space defined by 66 surface samples. Dots show the position of the trajectories interpolated to 100-year intervals. The oldest sample in each series is shown by a large diamond and the youngest by a circle with a crosshair. Large squares denote 3000 calendar years ago. The outlined areas include surface pollen assemblages from six major forest communities. Reproduced from Davis MB, Calcote RR, Sugita S, and Takahara H (1998) Patchy invasion and the origin of a hemlock-hardwoods forest mosaic. *Ecology* 79: 2641–2659.

and differences between the 16 individual stand histories (Figure 5). All stands move away from the rich deciduous forest indicated by pollen from alder, hazel, oak, and lime with some ash and elm. The commonest successional pathway is from birch and *Carpinus betulus* (European hornbeam) to forest comprising spruce and pine, although two stands became dominated by beech. The role of birch as a prominent taxon in forests undergoing transition from deciduous to coniferous was emphasized in the DCA, and many stands were at

this intermediate stage at AD 500. The same tendency was observed at the regional scale especially in the central region of the study area (Figure 4).

The DCA shows that unique successional pathways can occur and be resolved by stand-scale palynology, but the general pattern in southern Sweden during the last 3250 years has been along the pathways that lead to spruce – and to a lesser extent to beech-dominated stands. The spreading rate of spruce and beech into southern Scandinavia can be estimated from

Figure 4 Forest maps of southern Sweden from 1250 BC, AD 500, and the present based on regional pollen sites. The pie diagrams show data from stand-scale sites. Reproduced from Lindbladh M, Bradshaw RHW, and Holmqvist BH (2000) Pattern and process in south Swedish forests during the last 3000 years, sensed at stand and regional scales. *Journal of Ecology* 88: 113–128.

Figure 5 Detrended correspondence analysis (DCA) of 13 stand-scale sites from southern Scandinavia. Nine of the sites are represented by three time points (1250 BC, AD 500, and the present). Four sites cover just AD 500 to the present. The arrows show the direction in time. Reproduced from Lindbladh M, Bradshaw RHW, and Holmqvist BH (2000) Pattern and process in south Swedish forests during the last 3000 years, sensed at stand and regional scales. *Journal of Ecology* 88: 113–128.

the arrival times at the individual stands sampled by small hollows. Data–model comparison of species spread showed that the late Holocene spread of spruce was rather rapid (250 m year^{-1}) throughout the last 4000 years and was only limited by biological processes of dispersal, despite significant

Figure 6 The mean values for rate-of-change analysis for 13 stand-scale sites in southern Scandinavia. The analysis included the calibrated tree pollen data, shrub, and herbaceous taxa that exceeded 2% of the pollen sum in at least one sample. Std. DCs – chord distance per 100 years. Reproduced from Lindbladh M, Bradshaw RHW, and Holmqvist BH (2000) Pattern and process in south Swedish forests during the last 3000 years, sensed at stand and regional scales. *Journal of Ecology* 88: 113–128.

changes in climate. In contrast, the spread of beech was most likely controlled by site properties (Bialozyt et al., 2012).

Rate of vegetational change

Analysis of the rate of vegetational change indicates those time periods when rapid reorganization of forest composition occurred as well as periods of relative stability (Jacobson et al., 1987). Each stand-scale site in the study of records from Scandinavia has its own unique pattern, but certain common features are apparent when all stands are combined into a mean value (Figure 6; Lindbladh et al., 2000). A major increase in rate of change began around AD 1000 and has continued until the present day, with the last 1000 years showing an increase four times greater than that recorded during the preceding 2500 years. These recent changes thus completely overshadow the earlier record. The changes recorded from the last 150 years were the most rapid but represent the culmination of a transformation that was initiated 850 years earlier. Lindbladh and Foster (2010) combined data from 25 small hollows with six regional sites and confirmed the recent increased rate of change in south Scandinavian vegetation. They showed that while south Scandinavian oak populations had been in continuous decline for at least 2000 years, the majority of this decline took place during the last 300 years, corroborating historical records.

Anthropogenic or climatic control of recent dynamics of *T. cordata* and *Fagus sylvatica* in Denmark and southern Sweden?

Much debate focuses on the origins of beech forests in Northern Europe, primarily owing to their current dominance of large areas and their often presumed ‘natural’ status. At the continental scale, European beech is arguably in equilibrium with climate and thus is an expected component of modern southern Scandinavian forests. Paleoeological investigation of sediments in forest hollows in southern Sweden, however, indicates that present-day beech stands often show signs of

Figure 7 History of beech establishment and its relationship to large charcoal fragments recorded from a forest hollow at Siggaboda, southeast Sweden. Reproduced from Björkman L and Bradshaw RHW (1996). The immigration of *Fagus sylvatica* L. and *Picea abies* (L.) Karst into a natural forest stand in southern Sweden during the last 2000 years. *Journal of Biogeography* 23: 235–244.

Figure 8 Data model comparisons for lime (*Tilia*) and beech (*Fagus*) in Draved Forest, Denmark. Simulated data are percentage of total forest biomass, and observed data are calibrated pollen percentages from a mor humus profile. Reproduced from Cowling SA, Sykes MT, and Bradshaw RHW (2001) Palaeovegetation-model comparisons, climate change and tree succession in Scandinavia over the past 1500 years. *Journal of Ecology* 89: 227–236.

anthropogenic disturbance immediately prior to the replacement of *T. cordata* (small-leaved lime) by beech. Significant population expansions of beech were closely associated with fire episodes linked to anthropogenic activities at a forest hollow in Siggaboda, southeast Sweden, (Björkman and Bradshaw, 1996; Hannon et al., 2010; Figure 7) and the Siggaboda record is repeated at other sites in the region (Bradshaw and Lindbladh, 2005). Controversy, therefore,

concerns not so much whether beech should be present on a continental scale, but rather whether or not its dominance in southern Sweden and Denmark is a ‘natural’ feature of the landscape (i.e., having nonanthropogenic origins). Do climate-driven simulations of forest composition predict beech dominance for southern Scandinavia?

Simulations with a climate-driven forest stand simulation model in Draved Skov, Jutland, did not support the hypothesis

Figure 9 Suserup forest hollow, Denmark. Summary diagram showing selected trees recorded as pollen (filled curves) and macrofossils (●). The charcoal fragments are expressed as number per cm³. Reproduced from Hannon GE, Bradshaw RHW, and Emborg J (2000) 6000 years of forest dynamics in Suserup Skov, a seminatural Danish woodland. *Global Ecology and Biogeography* 9: 101–114.

that historical changes in climate were favorable for stand-scale dominance of beech (Figure 8; Cowling et al., 2001). The results indicated that, following cooling during the Little Ice Age, lime tree populations should have rapidly reestablished their dominance in deciduous forests. Observation, based on a stand-scale pollen analysis from mor humus in Draved Forest, recorded a replacement of lime by beech (Figure 9; Aaby, 1983).

Based on the results of climate-driven simulations, beech should not dominate modern-day northern temperate woodlands in Europe, whereas lime should be present in significantly greater quantities than are observed today (Figure 8). The minor presence of lime has been a long-standing feature of forests in Northwest Europe and can best be explained by anthropogenic interference. Forest clearance for agriculture followed by subsequent abandonment of fields favors the replacement of lime by beech, as does the introduction of domestic livestock into the forest (Björse and Bradshaw, 1998). Thus, the widespread late Holocene replacement of lime by beech in Northwest Europe was driven by anthropogenic forces even though forest changes of comparable scale earlier in the Holocene were climate driven.

Charcoal and macrofossils

Stand-scale forest structure and the importance of burning and forest grazing in the past are issues of conservation and management interest. Plant macrofossil and charcoal studies from southern Scandinavia have helped inform the debate about the degree of forest openness in the past, and relevant data have come from small forest hollows (Bradshaw and Hannon, 2004; Bradshaw et al., 2010; Hannon et al., 2010). The record from Suserup Skov, Denmark, covered the last 6000 years and contained abundant large fragments of charcoal from 5000 years ago until 1000 years ago (Hannon et al., 2000; Figure 9). The charcoal gave evidence of local burning, but the fires were almost certainly ground fires that maintained rather open conditions in the forest and kept out particularly fire-sensitive species. European beech, a very fire-sensitive species, only became abundant when the burning ceased while Scots pine, which tolerates moderate fire, was a natural component of the vegetation only during the periods of most frequent burning.

The plant macrofossil record at Suserup considerably broadens our knowledge of mid- to late Holocene forest composition in Denmark. It shows that both small-leaved lime and *Tilia platyphyllos* (large-leaved lime) grew on site about

5000 years ago as did *Quercus robur* (pedunculate oak) and *Q. petraea* (sessile oak). At this time, there is stand-scale evidence for at least 16 tree and shrub taxa, which is a unique record of diversity for Northwestern Europe that is unmatched in present woodlands. Suserup is a fertile, base-rich site, but its mid-Holocene record was probably characteristic of other similar as yet uninvestigated sites. Understanding the loss of this diversity is a research challenge that has relevance for the protection of European forest biodiversity at present.

Conclusions

Stand-scale palynology permits spatial resolution that provides detailed insight into dynamic vegetation processes that cannot be resolved using conventional pollen analysis. The case studies presented in this article give information about invasion mechanisms, forest structure, local diversity, succession, fire, and disturbance processes that link directly to topical issues in long-term ecological research and conservation biology. The recognition of the former importance of lime in northern and central European forests is one important conclusion from stand-scale studies. Stand-scale sites also link to conventional regional sites, where the research focus is on reconstruction of past climate and land cover. Thus, stand-scale sites provide a pivotal link between Quaternary science and ecology. The understanding of stand-scale sites has benefited from recent developments in pollen representation theory. A promising future application is their increased use in the validation and development of stand-scale forest simulation models.

Changing Plant Distributions and Abundances

T Giesecke, University of Göttingen, Göttingen, Germany

Introduction

The spread of plants is a continuous process and yet difficult to observe directly because plants are sessile organisms that spread through the dispersal of propagules (organs used for propagation). Natural plant distribution limits are generally set by species-specific climatic parameters that determine their survival and regeneration. However, these areas of potential distribution determined by climate are often more extensive than the actual species distributions (Svenning and Skov, 2004). These discrepancies might indicate that the distributions of many species are dispersal limited (Svenning and Skov, 2007), especially in high and mid-latitudes, where glacial cycles have repeatedly altered plant distributions. Recent concerns regarding the impacts of global change have raised the question of whether plant distributions can shift fast enough to keep up with the changing climatic conditions.

Plants may also spread when previously insurmountable barriers to dispersal are overcome. Over the course of millions of years, this can occur through the emergence of land bridges, with lowered sea levels, or the collision of continents and the closure of straits. Especially during the past 500 years, humans have both deliberately and unwittingly moved innumerable plants over dispersal barriers and thus altered many ecosystems.

The spread of plants can be studied on many different timescales: from the effect of alien species on ecosystems within a few years to subcontinental invasions of major trees lasting for several thousand years and the spread of plant families and genera between continents on the scale of millions of years. Knowledge of the dynamics and patterns of plant invasions is therefore gathered from different disciplines including paleontology and paleoecology, as well as ecology and genetics (Petit et al., 2004). Results of this research are important for evaluation of possible consequences of global warming for species distributions and abundance (Pitelka et al., 1997), as well as assessment of threats from introduced and genetically modified plants to ecosystem structure and biodiversity.

This article focuses on the reconstruction of changes in plant distribution and abundance based on pollen diagrams. The focus is therefore on the distribution of wind-pollinated trees, in subcontinental space, during thousands of years. New insights from DNA studies and numerical modeling contribute greatly to our current understanding, and these aspects are therefore included in this overview.

How to Gain Knowledge About the Spreading of Plants

Information on changes in plant distributions on short timescales can be obtained from a variety of sources such as air photos, satellite images, historical records, herbarium collections, or the age structure of invasive trees within an

area. Paleoecological techniques have to be used to reconstruct the temporal pattern in changes of plant distributions on longer timescales. Plant remains that preserve in favorable environments at or near their place of growth testify to the presence of that plant at the time when the material was deposited. By far, the most abundant plant remains are pollen grains, which preserve well in the sediments of lakes and bogs or in very dry environments. These environments also preserve larger plant remains like needles and seeds (macrofossils) or branches and stumps (megafossils). Both microscopic (pollen) and macroscopic (from bud scales to tree trunks) plant remains are used in reconstructing past plant distributions, yielding different perspectives.

Although the identification of fossil pollen grains is generally only possible to generic or even family level, as for many herbs, macroscopic plant remains are often identifiable to species level. Macrofossils are rarely transported over large distances, and their presence at a location therefore clearly indicates that the plant was present near the site. Macrofossils are often readily identifiable even in the field, and thus, it is not surprising that the earliest information on past vegetation came from macroscopic plant remains (Birks and Seppä, 2010). Andersson (1902) was able to compile the first map depicting past distribution limits of *Corylus avellana* (hazel) in Sweden with the help of many interested laymen who reported finds of hazel nuts outside the distribution of the shrub (Figure 1). At the time when Andersson compiled his map, it was impossible to directly obtain the age of the individual finds, and thus, the age of this northernmost occurrence of *C. avellana* could not be obtained. As in this example, macroscopic plant remains are often conspicuous and are thus discovered during peat harvesting, road building, and archaeological excavations or simply by chance. Tree stumps and trunks above or beyond the treeline are another example where evidence of past species' occurrence is easily found. Since the development of radiocarbon dating in the 1950s, such finds can be directly dated and thus represent a point in space and time, which together with other finds can yield a thorough assessment of past changes in species distribution.

Although macrofossils allow for spatially precise reconstructions, they often yield little information on the average upland vegetation composition, which is more readily obtained from pollen analysis. Moreover, pollen analysis often yields continuous information and inherently delivers some crude age control. The latter aspect was potentially the most important advantage at the time of the technique's development in the 1920s, in the research era before radiocarbon dating. As a consequence, macrofossil analysis received little attention in the decades following the 1920s, especially in Scandinavia, the birthplace of pollen analysis (Birks and Seppä, 2010).

Pollen analytical results, on the other hand, quickly became available, and only 8 years after von Post's 1916 lecture that established pollen analysis as a standard method, von Post

Figure 1 The present (hatched) and past distribution limit (line) of hazel (*Corylus avellana*) in Scandinavia redrawn from Andersson G (1902) Hasseln i Sverige fördom och nu. *Sveriges Geologiska Undersökning Series C 3*: 1–168. Dots mark the location of fossil hazel nut finds reported to Andersson.

(1924) published maps depicting the relative abundance of particular taxa during different time periods in southern Sweden. In these maps, the abundance of a particular taxon was depicted by circles with different radii, representing the pollen abundance of the taxon at the site. The number of available pollen diagrams also quickly increased outside Sweden. Thus, Szafer (1935) treated pollen percentages from 152 sites across Poland as if they were elevation data and produced the first isopollen maps, where the lines represent equal pollen percentages of a specific taxon at a given time. In his maps, he also decided on a threshold value to represent presence of the taxon in the area. The need for such threshold values represents the major handicap in using pollen analytical results to reconstruct past species limits. Wind-pollinated plants produce large amounts of pollen that is transported over vast distances, which makes it difficult to decide whether small amounts originated from locally occurring, but rare specimens or large, distant populations.

Since the time of von Post and Szafer, numerous pollen diagrams covering the last 10–15 ka have been produced from all continents and are an excellent source for studying changes in plant distribution and abundance on long timescales and over vast areas. To make better use of these invaluable datasets, they are collected into databases and made available through the internet. Reported macrofossils finds are also compiled into databases. In the new paleoecological database Neotoma, these datasets can be extracted in conjunction with pollen data.

The application of genetic techniques to the reconstruction of plant spreading has greatly enhanced our insights into patterns and processes, and the application of ancient DNA to these questions is poised to further change our perspectives (Gugerli et al., 2005). Geographical distributions of genetic

markers in plants reveal their kinship and make it possible to reconstruct the colonization routes of different lineages, which have changed established ideas about plant migration (e.g., Magri et al., 2006). The composition and diversity of genetic markers in extant populations gives insight into some of the processes in plant populations that were at work when the species were spreading 10 ka earlier (Petit et al., 2002b). Because plant spreading occurs over long time periods, it is difficult to gain knowledge from experimental, field observations or monitoring studies designed to test ideas. Dispersal theory has evolved models that offer robust methods to test hypotheses, to help understand past plant spreading, and to permit predictions for future scenarios (Clark et al., 1998).

Examples of Late Quaternary Plant Spreading

As a suite of research techniques, paleoecology developed in the mid- to high latitudes of the Northern Hemisphere, regions that changed dramatically between cold and warm stages of the Quaternary. Many plants that are widespread today were restricted to small areas under the climate that prevailed during the glacial intervals. Seen from today's perspective, these ranges are termed refugia (Bennett and Provan, 2008). The potential growth area for many of these plants increased rapidly when temperatures rose during the Late Glacial and the onset of the Holocene. In consequence, plants spread into these newly-available areas and competed for new habitats. However, the plant communities we know today did not move as belts, but species spread independently from each other and new combinations of different plants formed in time and space (Bennett and Provan, 2008; Davis, 1976; Huntley, 1988).

The Holocene changes in the distribution and abundance of deciduous *Quercus* (oak) and *Tilia* (lime) in Europe offer good examples of how the composition of forests changed through time (Figure 2). The maps in Figure 2 are taken from the atlas of past and present pollen maps for Europe (Huntley and Birks, 1983), which shows isopollen maps for European taxa in 500 or 1000 radiocarbon-year time steps. When comparing isopollen maps for different taxa, it has to be kept in mind that different trees produce different amounts of pollen, and it is therefore not possible to compare the numerical values directly. In this example, oak species are large pollen producers, and lime species disperse little pollen. Therefore, their respective pollen percentages were reclassified to improve visual comparison.

For the beginning of the Holocene (Figure 2(d)), lime pollen was frequently found only in sediments from southeastern Europe, while deciduous oak pollen was abundant in records from the Iberian, Apennine, and Balkan peninsulas. At about 10 ka, many east European forests contained lime but not oak, whereas the opposite was the case in western Europe (Figure 2(c)). In the following millennia, both lime and oak species were abundant in central European forests (Figure 2(b)), and it was mainly the abundance of lime that declined toward the present (Figure 2(a)).

Isopollen maps are a useful tool to present changes in plant abundance through time, but because each time slice is presented on a different map, it is difficult to extract

Figure 2 Map of changing distribution and abundance of deciduous oak (red) and lime (green) pollen at about (a) 2000 years ago, (b) 7000 years ago, (c) 10000 years ago, and (d) the beginning of the Holocene about 11500 years ago. The wide-hatched areas mark the distribution of frequent occurrences of deciduous oak and lime as indicated by more than 5 and 1% of their pollen, respectively. The narrow-hatched areas indicate regions where the tree comprised an important proportion of the forest indicated by 25 and 5% of their pollen, respectively. Percentages are based on the sum of tree pollen. Redrawn and simplified from Huntley B, and Birks HJB (1983) *An Atlas of Past and Present Pollen Maps for Europe 0–13000 Years Ago*, pp. 667. Cambridge: Cambridge University Press.

information on the dynamics of plant spreading or continental-scale changes in abundance patterns. An alternative approach is to choose a specific point on the pollen curve (e.g., a threshold value) and map the time of its occurrence in space. These maps depict lines of equal time for the occurrence of a specific event (isochrone maps) (Figures 3 and 4). Often, isochrone maps depict features in pollen diagrams that are interpreted to represent the moment when the species concerned has arrived in the immediate area surrounding a site (Birks, 1989; Davis, 1976). Such maps give valuable insight into the dynamics of a taxon's spread, but they simplify the problem of identifying the arrival of species from pollen data and often give the impression of a frontlike spread of a dense population.

The spread of *Picea abies* (Norway spruce) in Scandinavia provides a good example of this problem. When plotting the time that different threshold values were reached in the abundant pollen diagrams from Scandinavia and adjacent areas, a clear frontlike pattern emerges (Giesecke and Bennett, 2004) (Figure 3). On the basis of this analysis, the spread of Norway spruce occurred in the area of present-day Sweden <5000 years ago. However, several large Norway spruce remains (e.g., cones) extracted from peats in central Sweden date to the early Holocene (Kullman, 2001). Moreover, a few pollen records indicate the presence of the tree several thousand years before it became abundant (Figure 3). Some Finnish pollen diagrams even indicate an early Holocene presence and a later decline of spruce pollen. Furthermore, the spatial patterns of

DNA markers in mitochondrial and nucleus DNA from current Norway spruce populations suggest that the tree spread into Scandinavia from several different areas (Tollefsrud et al., 2008, 2009). The direction of spread reconstructed from pollen cannot explain the pattern of DNA markers and may be only one of the realized routes. The combined evidence suggests that Norway spruce spread into Scandinavia long before it became abundant and that this spread occurred without leaving a clear palynological trace. It is conceivable that a first spread, with only a low population density, followed the retreat of the ice sheet. Winged spruce seeds could have been transported over many kilometers in late winter on ice-crusted snow (Giesecke and Bennett, 2004). This could have led to small scattered populations, some of which subsequently declined while others grew only slowly and were too small to be detectable by conventional pollen analyses for thousands of years.

These contrasting patterns of palynological, genetic and megafossil evidence raise the question of what triggered the wave of expanding populations of Norway spruce during the late Holocene (Giesecke, 2004). It also shows that none of the three sources of information alone can accurately describe the Holocene history of Norway spruce in Scandinavia. Studies on ancient DNA from several sites are needed to obtain more evidence for enhancing our understanding of the postglacial history of this important tree species in Scandinavia.

The spread of deciduous oak species in Europe is a good example of how results from pollen analysis and a survey of

Figure 3 The spread of Norway spruce (*Picea abies*) in Fennoscandia and adjacent areas. Interpolation of the time the 5% threshold was reached in pollen diagrams. Circles show the position of pollen diagrams indicating small spruce populations deduced from the continuous curve or the 1% threshold at approximately 9000 = blue, 7000 = green, and 5000 years ago = red. Purple diamonds mark the position of diagrams with more than 3% spruce pollen during the Late Glacial.

Figure 4 Major spreading routes and dynamics for the spread of deciduous oak in Europe. The time of the beginning of the continuous pollen curve (rational limit) is represented by gray broken lines of equal time. Blue arrows mark the spreading routes reconstructed from extant haplotypes, and circles indicate proposed refugia: green = primary refugia deduced from pollen data; red = primary refugia additionally proposed from genetic data; yellow = secondary refugia. Adapted from Brewer S, Cheddadi R, de Beaulieu JL, and Reille M (2002) The spread of deciduous *Quercus* throughout Europe since the last glacial period. *Forest Ecology and Management* 156: 27–48; Petit RJ, Brewer S, Bordacs S, et al. (2002) Identification of refugia and post-glacial colonisation routes of European white oaks based on chloroplast DNA and fossil pollen evidence. *Forest Ecology and Management* 156: 49–74.

genetic markers in present-day populations complement each other to reconstruct spreading history. As mentioned previously, it is often not possible to detect small populations using pollen analysis, which is a hindrance when trying to gain information on where species were growing during the Last Glacial Maximum (LGM). The survey of genetic markers in living populations permits construction of the kinship between populations throughout Europe. Populations with a specific genetic marker (haplotype) in the south persisted during the northward spread of that population so that the route along which the population was spreading is marked today by individuals sharing the same haplotype. Not all populations with unique haplotypes succeeded in the race for new habitats. This effect is called a genetic bottleneck and results in detectable greater genetic diversity in the refuge areas, with lower genetic diversity toward the periphery of the taxon's range. In this way, genetic markers have been used to verify *Quercus* refugia that were identified from pollen analysis and to identify additional oak refugia (Figure 4). The combination of an isochrone map with proposed spreading routes of major haplotypes of oak (Figure 4) allows new insight into spreading history. The portrayal of the spreading routes takes account of obstacles like mountain ranges, while the isochrones represent an interpretation on a plane. It is interesting to note that the spreading routes are not always perpendicular to the isochrones, supporting the concept that the initial spread occurred at low population densities in a chaotic, rather than directional manner.

The geographic distribution of genetic markers in living *Fagus sylvatica* (beech) populations is another example of how the combination of pollen and DNA analysis reveals new insights into the postglacial spread of species (Magri et al., 2006). Pollen analysis suggested that beech populations occurred around the Mediterranean basin during the LGM and initial summaries suggested colonization from the Balkans toward the west (Giesecke et al., 2007). Genetic results support the location of these palynologically identified LGM populations but show that only a few LGM populations were the source of the northward and westward spread of the tree, while other populations in the south showed little expansion during the Holocene and did not contribute to the gene pool of northern beech populations (Figure 5). Svenning and Skov (2004, 2007) argue that different tree species have expanded their ranges from their refugia to a different extent. Here, we see an example where different populations of the same species behave differently. The data also demonstrate that the shortest distance between a population and the nearest glacial refuge area is not necessarily an indication of the direction of colonization.

Speed and Pattern: How Did It Work?

The Late Glacial and early Holocene spread of temperate and boreal trees for new habitats in treeless areas reached dispersal rates of over 1000 m year⁻¹. This rate incorporates the time that a tree needs to grow from seed to maturity (generation time), as well as the distance over which the seed has to be dispersed. By multiplying the spreading rate with generation time, one obtains the dispersal distance. For example, the early Holocene spread of oak in Europe shows spreading rates of 500 m year⁻¹, which, multiplied by a generation time of about

Figure 5 Distribution and Holocene spread of *Fagus sylvatica* (beech) in Europe. The green line marks the natural distribution according to *Atlas Flora Europaea* (Jalas J and Suominen J (eds.) (1972–99) *Atlas Florae Europaeae: Distribution of Vascular Plants in Europe*. Helsinki: The Committee for Mapping the Flora of Europe and Societas Biologica Fennica Vanamo) and the filled green areas the potential distribution of beech (Bohn U, Gollub G, and Hettwer C (2000) *Karte der natürlichen Vegetation Europas*. Massstab 1:2.500.000 Karten und Legende. Bonn: Bundesamt für Naturschutz). Red circles mark tentative location of refuge areas and arrows indicate main colonization routes (Magri D, Vendramin GG, Comps B, et al. (2006) A new scenario for the Quaternary history of European beech populations: Palaeobotanical evidence and genetic consequences. *New Phytologist* 171: 199–221).

30 years, amounts to a seed dispersal distance of 15 km. But acorns are heavy seeds and usually only found several meters from their parent tree. This mismatch between the seed dispersal distances that can be observed today and the distances necessary to explain early Holocene tree spreading is known as Reid's paradox of rapid plant migration (Clark et al., 1998). It is hard to imagine that many acorns are dispersed over 15 km, but it is possible that a single seed out of a population of many thousands is transported over long distances. Dispersal theory describes this concept with seed dispersal functions that have a high kurtosis: they predict that the greatest amounts of seeds will be dispersed close to the source but allow for a small number to be dispersed over long distances.

When applying this concept to the early Holocene spread of oak, it may be assumed that a single seed was deposited many km away from the nearest oak tree. If this seed germinated and grew into a tree, which in turn dispersed seeds that mostly fell close to the tree, this single tree would become the founder of a new population (Figure 6(c)). This mechanism seems to be the most likely explanation for the actual distribution of haplotypes in oaks of western France (Petit et al., 1997). Here, oak trees were sampled within a region with high resolution, and the distribution of chloroplast DNA markers was analyzed. In oaks, chloroplasts are inherited only from the mother (maternally) and thus through the heavy seed. The analysis revealed a mosaic with different areas dominated by distinct haplotypes. Thus, the population of oak trees in each of these areas may descend from one single founding tree, through the maternal line.

Genetic evidence has also yielded another possible mechanism for the high spreading rates that are reconstructed from pollen data. The haplotype distribution of *Fagus grandifolia*

Figure 6 Models of tree spread; broken lines mark dispersal: (a) Continuous moving front: dispersal takes place from a mature dense population to just beyond the distribution limit. (b) Advance as a discontinuous population: few discrete long-distance dispersal events lead to founder populations, which in turn expand and finally merge with each other. (c) Spread at low population density: frequent long-distance dispersal leads to small scattered founder populations, which are new sources for long-distance dispersal events. (d) Merging of disjunct populations: small scattered refuge populations expand and are a source for dispersal events as well as large distant populations. Both populations merge eventually. (a) and (b) Redrawn from Davis MB (1987) *Invasion of forest communities during the Holocene: Beech and hemlock in the Great Lakes region*. In: Gray AJ, Crawley MJ, Edwards PJ (eds.) *Colonization, Succession, and Stability*. Oxford: Blackwell Scientific.

(American beech) and *Acer rubrum* (red maple) in North America suggests that the glacial refugia of both trees were much further north than indicated by pollen data (McLachlan et al., 2005). These populations, which persisted as close as 500 km south of the ice margin, may have consisted of groups of trees in habitats with favorable microclimate (cryptic refugia) too small to be detected by pollen analysis (Figure 6(d)). These northern populations, as well as larger southern populations, expanded after the last glaciation. Without the recognition of these northern refugia, the expansion of these populations would be easily interpreted as a rapid spread of the more southern populations, resulting in apparent high spreading rates that never actually occurred.

However, many regions (such as those covered by ice sheets) were most certainly bare of any trees during the LGM and yet rapid spreading rates have been reconstructed for these areas (McLeod and MacDonald, 1997). Investigations of carefully selected and well-dated lake sediments allow the reconstruction of pollen accumulation rates (PAR), which is a better measure of changes in tree abundance than the interdependent percentage. The increase in PAR estimates of a pollen taxon can be used as a proxy for the population increase of the parent tree and compared to population growth models (Bennett, 1983, 1988). Such studies interpret the often exponential increase in PAR to represent the expansion of small populations that would have been present near the site even before the pollen type is encountered in standard counts.

The above interpretations on the mechanisms of plant spread are in contrast to traditional models of the frontlike

movement of a dense population (Figure 6(a); Davis, 1987). These traditional models find support in the observation of sharp distribution limits of present species ranges (Davis et al., 1991). The model of a moving front may be inferred from the presentation of species spreading in the form of isochrone maps and the common observation that regional population expansions often follow a wavelike pattern. However, the moving front model cannot explain exponential growth curves of PAR estimates (Giesecke, 2005) and regional pattern of haplotypes (Petit et al., 1997), and it also does not comply with theoretical models (Clark et al., 1998). The moving front model may therefore be inadequate to describe tree spreads on the continental or regional scale, although it may still be applicable on the local scale.

Distribution Versus Abundance

In a simple thought experiment, Bennett (1985) showed that, using pollen analysis, it should be impossible to detect a single tree of a given species in a forest of different species. What can be reconstructed from a network of pollen diagrams is the range of common occurrence of a species. A good example to illustrate the difference between the species distribution limit and the area of abundance can be seen for European beech (*F. sylvatica*) in Figure 5. The *Flora Europaea* (Jalas and Suominen, 1972–99) marks the simple occurrence of the species within a 50 by 50 km square, while the map of the potential natural vegetation (Bohn et al., 2000) shows areas where beech would be the dominant or characteristic tree. The latter is the area that can be reconstructed from pollen diagrams, while the former is generally invisible in reconstructions from pollen.

For some species, colonization is directly followed by population expansion and, assuming the rate of expansion is equal at all sites, it is possible to deduce the underlying spreading rates (Bennett, 1986). However, the rate of population expansion can vary between sites (Giesecke, 2005; Giesecke et al., 2007) or the species may spread at low population densities and expand thousands of years later. The possible occurrence of cryptic refugia (see Stewart and Lister, 2001) complicates matters even more, so that published rates of spread based on paleoecological data are potentially erroneous and need careful revision.

On the other hand, once a population has exceeded its detectable size, then pollen analysis is well suited to reconstruct changes in abundance. Many of the factors that might influence the spread of a species will also be important for changes in its abundance. Moreover, for some species, like Norway spruce, the questions have changed from analyzing its postglacial spread to understanding its late Holocene population expansion or the lack thereof during the early Holocene.

Factors Influencing the Spread of Trees and Changes in Abundance

The vegetation history of temperate and boreal trees in the Northern Hemisphere shows that some trees spread rapidly, following the warming at the end of the last glaciation, while others lagged behind, and some spread much later during the

Holocene. Many factors have been discussed to explain these patterns, which can be summarized as follows:

- *Seed dispersal.* The small winged seeds of *Betula* (birch), for example, can easily be picked up by storms and carried over large distances. The dispersal organs of plants may have a different likelihood of becoming dispersed over long distances. This factor, combined with different generation times, results in different theoretical rates of spread. Thus, it can be argued that the time at which a species arrives in a certain place is largely determined by the average spreading rate and the distance from its LGM refugia, taking into account obstacles like mountain ranges.
- *Competition between species.* Many light-demanding species are also good colonizers and thus dominated early phases of forest establishment during the Late Glacial and early Holocene. The trees that followed after had to compete with those that were already established. This interpretation finds support in the observation that many shade-tolerant species often need many generations at one site before they became abundant.
- *Soil development.* Young soils that developed from glacial deposits were rich in nutrients (especially phosphorous), which leached out over time. The growth of peat mosses changed nutrient-rich mires into nutrient-poor raised bogs, and blanket peats developed in formerly forested areas. Thus, changing soil properties may change the competitive balance between species. However, a change in vegetation cover can also cause a change in soil type (Willis et al., 1997), and it is therefore questionable if soil leaching could have been the driver for late Holocene tree spreads or changes in abundance.
- *Changes in forest disturbance.* Natural disturbance regimes, such as fire and storms, have changed in frequency which may influence the balance between species with short versus long generation times. There is clear evidence in Europe that human activity has significantly changed the vegetation over the last 3000–8000 years. By opening the forest, human activity at least accelerated the population expansion of late-spreading trees, and it may even have facilitated it. The utilization of the forest by humans and their domesticated animals also altered the competitive interaction between trees, which may also have allowed species to spread into areas from which they would have been otherwise excluded by competition.
- *Climate change.* The hypothesis that regional Holocene climate change has the potential to explain most patterns of tree spreading is difficult to test because pollen diagrams themselves are the most abundant proxy record of past climate, which leads to circular arguments. Arguments for climate-controlled late Holocene tree spreads are therefore often made by rejecting all alternative hypotheses (Tinner and Lotter, 2006). Advances in modeling Holocene climate, combined with vegetation modeling, will make it possible to further test this hypothesis.
- *Adaptation and gene flow.* Widespread tree species grow under different climate parameters in different parts of their range and often show specific adaptations to those climate parameters. If the acquisition of specific adaptations is slow, then this could explain the delayed spreading of some species (Davis and Shaw, 2001).

Conclusion

Results of paleoecological investigations have yielded abundant information that allows the reconstruction of continental-scale changes in plant abundance. Recent results from surveys of genetic markers in present-day populations reveal colonization pathways, which often differ from the interpreted direction of spread obtained from paleoecological data. This leads to the interpretation that the initial spread of species after the LGM occurred at low abundances and that populations may have expanded only several thousand years later. Inferences about spreading rates are therefore only possible for species where the spread was immediately followed by population expansion. Many of the rates published so far are potentially erroneous and should therefore not be used in studies predicting the impact of climate change on species distributions.

Paleoecological data are well suited to demonstrate past changes in species abundance and have already revealed contrasting patterns of population expansion. Therefore, further research should aim at uncovering the mechanisms and drivers behind the different continental-scale patterns of population dynamics. Genetic studies may yield further surprises, and the utilization of fossil DNA may open a new chapter of research into the processes behind past changes in species distributions and abundances.

The Biome Approach to Reconstructing Past Vegetation

Introduction: Reconstructing Late Quaternary Vegetation at Large Spatial Scales

When vegetation change is viewed at continental scales, dynamic biogeographic patterns become apparent. Individual taxon ranges shift markedly and whole vegetation formations appear, fragment, or disappear through time. If we assume that large-scale distribution patterns of vegetation are, on millennial timescales, mainly controlled by climate, such changes are likely to reflect variations in key atmospheric circulation features, such as the spatial extent of a monsoon system or the average position of the polar jet and associated storm tracks. These in turn are affected, for example, by orbital variations or the presence of a large ice sheet. Features at this scale are those most effectively simulated by general circulation models (GCMs). Given the present need to model climate reliably in relation to increasing levels of atmospheric CO₂ (Randall et al., 2007), it is important to know how well climate models simulate climates different from those of the present day. Climate model performance can be assessed through the comparison of vegetation predicted from a paleoclimate simulation with actual past vegetation as recorded by paleodata. The approach was first developed for the COHMAP (1988) project and has evolved into the biome approach to vegetation reconstruction (Prentice and Webb, 1998).

This article explains the basis of 'biomization' (Prentice et al., 1996), which uses a globally applicable algorithm to generate maps of vegetation biomes from large arrays of pollen data; it then summarizes the results of the BIOME 6000 project (Prentice and Webb, 1998), which mapped vegetation at 0, 6000, and 18000 ¹⁴C years BP. Further sections discuss insights gained into Quaternary plant biogeography, illustrate model-data comparisons and briefly discuss new related approaches to vegetation reconstruction.

Objective Vegetation Mapping

It is difficult to make a map of modern global vegetation using a consistent and repeatable procedure, and mapping past vegetation is even more challenging. Disparate interpretations of past vegetation due to differences in regional approaches and/or paleoecological methodology make inter-regional compilations of interpreted data difficult, and attempts make global maps of paleovegetation have been subjective and hard to replicate. The biome method provides some distinct advantages over other approaches. It uses an objective and repeatable method to group pollen assemblages (the primary data) directly into globally consistent vegetation types (biomes). These reflect the structure and function of constituent taxa rather than their floristic identity. Maps for a given time slice (e.g., 6000 years BP) are created by assigning a dot, color coded for a particular biome, to each site that has a record. Such maps have relatively coarse spatial detail, but

they are generally preferable to those created by subjective interpolation among data points, especially if the latter mask areas of poor data coverage.

Paleoclimate Reconstructions

The biome method also provides a robust approach to investigate past climate. Reconstructions of past climate from paleodata usually follow the taxon-based transfer-function approach in which numerical relationships are developed between (for example) modern pollen abundances and observed climate variables. The numerical function is applied to fossil pollen assemblages and past climate variables are calculated. This method is constrained by observable modern relationships. In the past, certain taxa occurred in abundances observed nowhere today, and fossil pollen spectra may have no recognizable modern counterpart – so-called 'no-analogue' assemblages (Williams and Jackson, 2007). Once outside the envelope of modern observations, fossil pollen spectra, described in terms of taxon abundance, cannot be reliably related to past climate. The problem becomes acute for times prior to the Holocene, when the climate system and global vegetation were markedly different from today. The biome approach circumvents this problem: plant-climate relationships are described with reference to plant structure and function and are not dependent upon the fossil pollen assemblages having modern counterparts. The vegetation distributions thus obtained can be checked for concordance with those derived from climate-model simulations using the same bioclimatic rules.

The Biome Approach

PFTs and Climate

The distributions of plant species are partly controlled by bioclimatic factors, for example, their susceptibility to heating, cooling, or frost, and a minimum requirement for growing-degree-days. Various classification systems for global vegetation are based on this principle, for example, Holdridge's (1967) life zones. Associated with these bioclimatic responses are morphological and physiological plant traits that equip plants to succeed in certain environments but usually mean they are less suited to others. For example, in the cold conditions of the far North growing-degree-days are below the minimum for the growth of trees. All Mediterranean floras are characterized by species that are drought- and fire-tolerant, although there is little overlap in floristic composition among the Mediterranean regions of the world (Archibald, 1995). Thus global vegetation can be described according to the plant functional types (PFTs) that dominate in various types of climatic conditions, and these PFT assemblages can be classed as formations or biomes, such as arctic tundra or warm temperate evergreen sclerophyll forest. In this type of

classification, species identity is not paramount. Furthermore, the known bioclimatic tolerances of PFTs theoretically allow, and do indeed predict, novel admixtures – no-analogue biomes – under certain climatic conditions.

Climate is, of course, not the only factor affecting plant distribution. Disturbance regimes, differing growth strategies, and interspecific competition also play a role in determining which PFTs dominate a region. For example, drought, fire, and regeneration potentially all affect the balance of grassland and woodland at the moister borders of Savanna and temperate grassland regions (e.g., Scott, 1995). Soil and topography also influence vegetation, occasionally at regional scales, but more often on a local basis that is not resolved in continental-scale reconstructions.

Modeling Vegetation

If bioclimatic requirements and growth rates, regeneration, and competition are taken into account, it is possible to model modern global vegetation effectively. Prentice et al. (1992) developed a global vegetation model (BIOME) that incorporated these principles. BIOME can be fed data from modern climate observations or a climate-model simulation and will produce a vegetation map for those conditions (see Figure 1). In the case of simulations, these may also be paleo-simulations or simulations based on future projections of climate. Later, improved versions of BIOME account for variations in atmospheric CO₂ and other parameters that have a major effect on plant growth and distribution (see, e.g., Kaplan et al., 2003). It is an equilibrium model; for a prescribed climate it generates an optimal vegetation map based on a global grid of points, but it does not incorporate any subsequent interactions of climate and vegetation. More recently dynamic vegetation models such as the Lund–Potsdam–Jena model (Sitch et al., 2003) have been developed and interactive vegetation packages are now incorporated into GCMs. In this way, feedbacks related to vegetation–atmosphere interactions (such as albedo and moisture fluxes) can be modeled. As they are modified and improved, climate models require continual

evaluation. Mapped paleodata play a central role because they can be directly compared with simulated vegetation maps that are in turn driven by climate-model output in so-called data-model comparisons (see below).

Classifying and Mapping Pollen Data as Biomes – Biomization and the BIOME 6000 Project

In a global vegetation reconstruction, biomes should have distinct and realistic ecological qualities, and they must also be distinguishable from other biomes by pollen assemblage composition. In order to compare observed past vegetation with simulated past vegetation, biomes should be consistent with those defined in a vegetation model (such as BIOME). Although these requirements constrain the number of biomes that can be defined, this is not a problem – too many, and the biomization and resultant maps become unnecessarily complicated. Conversely, information may be lost if there are too few biomes. The ideal number depends upon the questions being asked of the data. For example, 18 biomes were used in the BIOME 6000 overview reconstructions for the northern continents and Africa (Prentice et al., 2000), and these included one tundra biome. In contrast, for a more detailed investigation of the Arctic, Bigelow et al. (2003) defined five separate tundra biomes.

Pollen-based biomes are defined using the biomization approach (Prentice and Webb, 1998; Prentice et al., 1996). Because pollen assemblages are conventionally reported as frequency data, the percentage values of pollen taxa are used as the basis of the biomization procedure. An algorithm that relates the taxon abundances in a pollen spectrum to PFTs and PFTs to biomes is then applied to each fossil pollen spectrum from a region of interest. The biome that has the highest resultant score is selected in each case (see Figure 2 for further details).

The biomization of modern pollen samples is validated by comparison with descriptions of modern vegetation. This is not as straightforward as it may seem, because regional vegetation maps are not easily amalgamated, nor are different

Figure 1 A comparison of mapped modern vegetation for the Arctic and sub-Arctic, the vegetation simulated by the BIOME 4 using a modern climate dataset as input and modern biomes based on biomized pollen spectra. Reproduced from Kaplan JO, Bigelow NH, Bartlein PJ, et al. (2003) Climate change and arctic ecosystems II: Modeling paleodata-model comparisons, and future projections. *Journal of Geophysical Research* 108(D19): <http://dx.doi.org/10.1029/2002JD002559>; Bigelow NH, Brubaker LB, Edwards ME, et al. (2003) Climate change and arctic ecosystems I: Biome reconstructions of tundra vegetation types at 0, 6, and 18 radiocarbon ka in the Arctic. *Journal of Geophysical Research* 108(D19): <http://dx.doi.org/10.1029/2002JD002558>.

Steps in biomization

1. Assemble and check original pollen data, then convert to %
2. Define a set of biomes (regional or global coverage)
3. Define a set of plant functional types (PFTs)
4. Define the biomes by their constituent PFTs
5. Assign all recorded pollen taxa to one or more PFTs

A simple example with 2 taxa, 3 PFTs, and 2 biomes is shown here

Taxon		PFT	
<i>Betula</i>			
<i>Picea</i>			
		Boreal-arctic deciduous broadleaved shrub: PFT contributes to the shrub-tundra biome	Boreal summergreen deciduous broadleaved tree: PFT contributes to the taiga (boreal evergreen forest) biome
		Boreal evergreen needle-leaved tree: PFT contributes to the taiga biome	

6. Assign taxa to biomes in a taxon-biome matrix (presence/absence)

	Taiga biome	Tundra biome
<i>Betula</i>	1	1
<i>Picea</i>	1	0

Example pollen values:
Betula 70%
Picea 30%

7. Calculate affinity score of each taxon for each biome (the following is taken from Prentice and Webb 1998,

$$A_{ik} = \sum_j \delta_{ij} \sqrt{\{ \max[0, (p_{jk} - \theta)] \}}$$

Where A_{ik} is the affinity of pollen sample k for biome i ; summation is over all taxa j ; δ_{ij} is the entry (0 or 1) in the taxon-biome matrix; p_{jk} are pollen percentage values; θ is a threshold pollen percentage.

Underlying this equation is the selection of taxa (taxon-biome matrix entries), the summing of the square roots of the percent values of taxa in a given biome, and the chance to set the threshold percent >0 , that is, to exclude very small pollen values that may be due to long-distance transport of grains from beyond the region of interest.

Assuming the threshold is zero for convenience, $\sqrt{70} = 8.36$ and $\sqrt{30} = 5.47$; therefore the total affinity score for shrub tundra is **8.36** (from *Betula* via the shrub PFT) and the total affinity score for taiga is $8.36 + 5.47 = \mathbf{13.84}$ (from *Betula* via the deciduous tree PFT and *Picea* from the evergreen tree PFT). The assigned biome in this simple example is therefore taiga (evergreen boreal forest)

Figure 2 Steps in biomizing a simple pollen spectrum.

global vegetation maps mutually consistent (Prentice and Webb, 1998). Biomizations have been validated for several continents, using regional maps and/or vegetation data reported with the modern pollen samples (e.g., Bigelow et al., 2003; Figure 1). Visual inspection of the maps shows generally good agreement, although there is some level of error in biome assignments. In some regions, modern vegetation reflects considerable alteration by humans, but even in these areas modern biomizations appear 'realistic' in relation to our understanding of potential natural vegetation (Prentice et al., 1996).

The BIOME 6000 Project

The BIOME 6000 project has produced pollen-based biome maps for much of the globe for 0 and 6000 ^{14}C years BP, and

there are also maps for 18 000 ^{14}C years BP for many regions. The exercise involved hundreds of participants worldwide. Regional experts screened radiocarbon-dated pollen data for taxonomic and chronological reliability, related pollen taxa to one or more PFTs, and assigned each PFT to one or more biomes. Fossil pollen spectra dated to within 500 radiocarbon years of 6000 ^{14}C years BP and within 1000 years of 18 000 ^{14}C years BP were then biomized and the results presented as maps of past biome distributions. Table 1 summarizes the publications in which biome reconstructions can be found; for a useful overview of the climatological and biogeographic implications of the past biome distributions see Prentice et al. (2000). Figure 3 presents biome maps for 0, 6000, and 18 000 ^{14}C years BP. The next section describes some of the prominent biome shifts and mentions probable climatic causes.

Table 1 Published biome reconstructions for 0, 6, and 21 ka

<i>Region/Topic</i>	<i>Publication</i>
Overview of the BIOME 6000 project and methods	Prentice and Webb (1998)
Overview of the northern continents and Africa 0, 6, and 18 ka	Prentice et al. (2000)

North America (East) late Quaternary	Williams et al. (2000)

Two issues of the *Journal of Biogeography* contain most of the BIOME 6000 vegetation reconstructions for different regions at 0, 6, and 21 ka: Volume 25, No. 6 (November 1998) and Volume 27, No. 3 (May 2000).

Global Vegetation Patterns at 18 000 and 6000 ¹⁴C years BP (18 and 6 ka)

The Last Glacial Maximum

The Last Glacial Maximum (LGM; 18 000 ¹⁴C years BP or 18 ¹⁴C ka) represents an interval when insolation patterns (as controlled by orbital cycles) were similar to present, but in almost every other aspect conditions were markedly different. Ice sheets were extensive across northern land regions, oceans were cooler, atmospheric dust loadings were higher, and CO₂ levels were lower (COHMAP Members, 1988; Jansen et al., 2007). All these features contributed to global climate and growth conditions that contrast greatly with those of today. Paleocological data for the LGM are relatively sparse compared with the data available for the Holocene, but their synthesis nevertheless reveals useful patterns.

The northern continents

Much of the Arctic region was under ice at the LGM. To the South of the ice and across unglaciated Beringia (North-West Canada, Northern Alaska, and North-East Siberia) tundra vegetation dominated (Edwards et al., 2000). Boreal forest was displaced to more southerly latitudes, and its overall extent contracted. In Eurasia particularly, steppe vegetation was far more extensive than today (Tarasov et al., 2000). In the mid-latitudes of Europe temperate deciduous forests and Mediterranean forests and woodlands were also greatly reduced and in many areas replaced by steppe (Elenga et al., 2000). In China, total site coverage is sparse, but a marked reduction of forest over much of Central China is evident in the data (Yu et al., 1998). The predominance of treeless biomes reflects heightened aridity as well as lower temperatures.

The lower latitudes and Southern Hemisphere

In the tropics and subtropics the data are sparser than for northern temperate regions, but they nevertheless clearly indicate major changes in vegetation cover, particularly the fragmentation and reduction in area of tropical moist forest in Africa (Prentice et al., 2000). The desert regions of South-West North America were characterized by conifer woodland; this has been shown to be the consequence of winter storms and rain linked to a southward displacement of the jet stream that was in turn due to intense high pressure over the Laurentide Ice Sheet (COHMAP Members, 1988; Thompson and Anderson, 2000). Globally, the extents of most other desert regions were similar to or greater than today's, reflecting generally greater aridity under cooler global climates. In Australia, the LGM vegetation was characterized by increased dominance of xerophytic PFTs over today, both in the southeast and the northern tropical region, indicating greater aridity (Pickett et al., 2004).

The mid-Holocene

During the middle Holocene (conventionally represented by 6000 ¹⁴C year BP or 6 ka in model simulations) Northern Hemisphere summer insolation was considerably greater than modern. By this time the waning northern ice sheets approximated their modern extent, so there was virtually no influence of residual Pleistocene ice on regional climates (eastern Canada is the one exception – see below). As Prentice and Webb (1998) point out, 6 ka does not represent a global climatic 'optimum' or even 'maximum.' The term 'climatic optimum' is ecologically meaningless because different plant species have different climatic requirements, nor was the warmest period of the Holocene experienced at the same time in all regions. Nevertheless, global average temperatures were most likely 1–2 °C warmer than present, and this makes 6 ka a particularly interesting period to study. The site coverage is generally good, and biomized data allow quite detailed comparisons of modern and 6 ka vegetation distributions.

The northern continents

The arctic treeline advanced northward by up to a few hundred kilometers over its current position in some regions, such as Central Siberia, reflecting warming due to heightened summer insolation. In contrast, forest in Eastern Canada was displaced to the south of its present limits as a result of residual Laurentide ice over Labrador (Bigelow et al., 2003; Dyke, 2004). In temperate Europe, thermophilous temperate forest expanded north of its current position and also southward into Mediterranean regions (Elenga et al., 2000). Steppe vegetation expanded slightly in North America, compared with current limits, but in China this did not happen; instead an enhanced monsoon due to higher summer insolation likely favored the broad distribution of temperate deciduous forest (Yu et al., 2000). In Japan, temperate coniferous forest was prominent, possibly favored over today's broadleaved evergreen/mixed forests by increased seasonality driven by warmer summers (Takahara et al., 2000).

The lower latitudes and Southern Hemisphere

Striking differences in vegetation cover between 6 ka and present are observed in the subtropics, notably in Africa,

Figure 3 Biome maps for the northern continents and Africa: LGM and mid-Holocene. From Prentice IC, Jolly D, and BIOME 6000 participants (2000) Mid-Holocene and glacial-maximum vegetation geography of the Northern continents and Africa. *Journal of Biogeography* 27: 507–519. Biomes for Australia not shown. Pickett EJ, Harrison SP, Hope G, et al. (2004) Pollen-based reconstructions of biome distributions for Australia, Southeast Asia and the Pacific (SEAPAC region) at 0, 6000 and 18,000 ^{14}C yr BP. *Journal of Biogeography* 31: 1381–1444.

where the biomization suggests that much of the modern Sahara was vegetated by grasslands and scrub-woodland (Jolly et al., 1998; Prentice et al., 2000). This feature appears to be related to a far stronger monsoon driven by summer insolation that was greater than present. However, tropical moist forest extent may have been less than

present; the enhanced monsoon further North may have been linked to less consistent rains near the Equator (Prentice et al., 2000). Relatively small differences between modern and 6 ka vegetation in Australia appear largely to reflect regional variations in moisture availability (Pickett et al., 2004).

Historical Biogeography: Migrations, Refugia, and Novel Biomes

BIOME 6000's global paleovegetation maps illustrate the dynamic nature of late-Quaternary biomes. The synthesized datasets can be used to investigate whether biome distributions changed in response to climate change, or whether biomes were fragmented or even disappeared entirely. Furthermore, in-depth examination of the taxon contributions to various biomes reveals considerable variability in biome composition through time.

Migration Versus Refugia

Temperate deciduous forest and tropical moist forest were both greatly fragmented during the LGM. Nevertheless, their constituent taxa survived and later assembled to form widespread forest biomes in the Holocene. For example, the deciduous forest was virtually eliminated from mainland China (Yu et al., 1998). Prentice et al. (2000) argue that while it is possible that the biome was displaced onto continental shelf areas that were subsequently inundated, the pollen data show that deciduous tree taxa also survived scattered within other biomes that were more widespread in the LGM, such as broadleaved evergreen forest. Thus *in situ* survival may have been as important as migration. Understanding how and where taxa survived major environmental changes and what ecological and evolutionary processes affected them is of relevance to evolutionary biology and conservation biology (see Harrison et al., 2001; McMahon et al., 2011; Qian and Ricklefs, 2000). Species distributions are once again being radically altered, this time by direct human action (such as transformation of ecosystems for agriculture and forestry), and contemporary biomes are threatened with disruption by climate change associated with global warming.

Temporal Changes in the Composition of Biomes

Steppe and tundra in the LGM

In certain cases, the biome assignment is sensitive to how a few 'indicator' taxa are assigned to PFTs (Prentice et al., 2000). This is the case for steppe and tundra biomes across Eurasia and Beringia in the LGM (Edwards et al., 2000; Tarasov et al., 2000). In Alaska and North-West Canada, the LGM pollen assemblages are assigned to tundra, but those further West and South in Eurasia are assigned to steppe, whereas sites in between are sensitive to the details of the biomization. Today, boreal forest tends to separate steppe and tundra geographically (see, e.g., Scott, 1995) and, for the most part, steppe and tundra are well differentiated functionally and floristically. However, if we explore the potential climate space (seasonal conditions of temperature and moisture) occupied by these biomes, we find that under conditions that are too cold and/or dry for forest (as in the LGM), steppe and drier forms of tundra are adjacent biomes and share similar dominant PFTs (grasses and forbs; Kaplan et al., 2003; Figure 4). Thus, underlying the instability in the biomization of the steppe-tundra transition in Eurasia is the fact that tundra and steppe are closely related (in terms of PFTs and geographic distribution) under certain configurations of climate.

Figure 4 Diagram after Kaplan et al. (2003) showing the climate space for northern biomes. Grass-forb tundra occurs in dry climates that are too cool for true steppe.

Paleoecologists have long questioned the nature of the treeless LGM vegetation of Beringia. It is associated with the presence of diverse Pleistocene megafauna including both herbivores and carnivores and must, therefore, have been productive enough to sustain this extensive faunal ecosystem (see Hopkins et al., 1982). The dominant pollen taxa, comprising grasses, sedges, and *Artemisia* (sagebrush, mugwort), have been interpreted as indicating either tundra or steppe (see above). Neither interpretation is convincing, because debate has focused on the modern properties of tundra and steppe ecosystems. Neither appears a suitable analogue for past conditions. Most modern tundra types are moist and dominated by woody plants that would not support large populations of specialist grazers, and modern steppe grows under conditions that are far warmer than those of the LGM in Beringia.

The refocusing of attention on which PFTs occur in cool, dry climate space, and the possibility that in the LGM Beringian 'tundra' was quite unlike contemporary tundra in both PFT composition and ecological properties, offers a promising solution to a long-standing biogeographic conundrum. In their biomization of northern tundra and boreal ecosystems, Bigelow et al. (2003) defined a grass- and forb-dominated tundra biome (GFT) associated with cool, dry climate space. Such vegetation is rare today in the Arctic, but where it does occur it is associated with locally xeric conditions (Yurtsev, 1982). In the biomization, many LGM pollen spectra across Beringia were assigned to this biome. In addition, the BIOME model output based on LGM paleoclimate simulations showed a high level of productivity for GFT, suggesting that it may have been able to support LGM herbivores (Kaplan et al., 2003). The lesson to be learned here is that our conceptions of biomes rely almost entirely on those that exist currently, whereas we should expect both variability in biomes through time and

different regional sets of biomes during the highly variable climatic conditions of the Quaternary.

Late Quaternary biomes of Eastern North America

Although the BIOME 6000 project focused on just two past time slices, in part because these times were the foci for coordinated climate-model experiments, more highly resolved histories of biome distribution during the late Quaternary are feasible. Williams et al. (2004) produced maps of biome distributions from the LGM to present at 1000-year time slices for Eastern North America (Figure 5). The maps' fine detail is based on a conservative, quantitative interpolation technique and thus the actual data points are obscured. This format has the advantage of illustrating clearly the continual shifting of biome distributions through time and the marked change in dominant biomes from the Late Glacial to the Holocene, but the details are likely to be inaccurate. Williams et al. (2004) also analyzed the changing composition of given biomes through time. For example, cool mixed forest, characterized by conifers, broadleaved trees and shrubs, and herbs, shows changing frequencies of these types through time. In particular, conifers dominate LGM and Late Glacial records, whereas after ca. 6 ka, broadleaved taxa are more abundant than conifers. Among the conifers, *Pinus* (Pine) and *Picea* (Spruce) dominate LGM and Late Glacial records, whereas *Tsuga* (Hemlock) dominates in the later Holocene (Figure 6). Biomizing, by definition, masks changes in taxonomic composition because the PFT–biome relationship drives the method. However, 'deconstruction' of biome composition provides interesting ecological insights and raises questions about the degree to which climate and non-climatic factors each determine these intra-biome changes.

Climate-Model Evaluations Using Biomized Data

As mentioned above, a key aim of the BIOME 6000 project is to produce mapped past vegetation at a global scale in order to evaluate the performance of climate models. It is assumed that the biome configurations of 6000 and 18000 ^{14}C year BP reflect the climate prevailing at those times, that is, large-scale patterns of vegetation are in equilibrium with the observed climate – an assumption that is not unreasonable for these two key times (Prentice and Webb, 1998). Reproduction of those configurations by a vegetation model such as BIOME driven by climate-model simulations is most parsimoniously interpreted as reflecting a successful simulation. If simulation and paleodata disagree, both must be revisited to assess where errors lie.

The Arctic Treeline

This exercise is usefully illustrated by the status of arctic treeline (i.e., the northern limit of the boreal forest) at 6 ka. As mentioned above, the biomized 6 ka treeline is strongly asymmetric latitudinally. A mid-Holocene northward advance might be expected with greater summer insolation, particularly in areas of continental climate, such as Siberia. The model simulations adopted in the data-model comparison by

Figure 5 Biome maps for North America at 1000-year time slices, from Williams JW, Shuman BN, Webb T, Bartlein PJ, and Leduc PL (2004) Late-Quaternary vegetation dynamics in North America: Scaling from taxa to biomes. *Ecological Monographs* 74: 309–334. Note that dates are calibrated to calendar years BP. Key to biomes: CCON, cool conifer forest; CDEC, cold deciduous forest; CLMX, cool mixed forest; CWOD, conifer woodland; DESE, desert; MXPA, mixed parkland; SPPA, spruce parkland; STEP, steppe; TAIG, taiga; TDEC, temperate deciduous forest; TUND, tundra; WMMX, warm mixed forest; XERO, xerophytic scrub.

Figure 6 Changes in biome composition through time for North American biomes, from Williams JW, Shuman BN, Webb T, Bartlein PJ, and Leduc PL (2004) Late-Quaternary vegetation dynamics in North America: Scaling from taxa to biomes. *Ecological Monographs* 74: 309–334. The graphs show long-term means of pollen percentages (for PFTs or taxa) for all sites assigned to the cool mixed forest biome (total number of sites shown by the gray histogram in the uppermost graph).

Kaplan et al. (2003) drive such a response in the BIOME model; they also show the treeline displaced northward in Canada, in contrast to the data. This data–model discrepancy can be explained by the last remaining Laurentide ice, which physically prevented the northward advance of vegetation as well as creating regionally cool conditions (Dyke, 2005). This feature was not included in the modeling, and the southward treeline displacement was not simulated.

The West African Monsoon at 6000 ^{14}C years BP

The ‘greening’ of the Sahara is one of the most striking features of vegetation in the Mid Holocene (see above). For some time it has been clear that the primary driver of this feature was the enhanced monsoon related to higher summer insolation in the Northern Hemisphere (e.g., COHMAP Members, 1988). Data on the biomes of the Sahel and Sahara regions were used as benchmarks against which to test model simulations. Could

Figure 7 Data-model comparison for West Africa at 6 ka from Broström A, Coe M, Harrison SP, et al. (1998) Land surface feedbacks and paleomonsoons in Northern Africa. *Geophysical Research Letters* 25: 3615–3618. The shading shows simulated vegetation according to the biomes described in the color key. The top panel shows the modern control. All other panels show a different 6-ka simulation. In these panels the paleodata data points are indicated by small circles (same color code), and the simulated vegetation is shaded. R = orbital forcing only; RVS adds vegetation feedback; RVSL adds prescribed lakes (including mega-lake Chad, see [Africa during the Late Quaternary](#)); and RVSLW adds prescribed wetland areas. The simulated climate becomes progressively wetter further North with the addition of more feedbacks into the model, and simulated vegetation better matches (but not perfectly) the observed vegetation.

models simulate enough precipitation far enough north to support the observed biomes of xerophytic woodland and grassland? Until recently paleoclimate models incorporating the insolation anomaly but no surface feedbacks consistently failed to simulate the full magnitude of the feature. Models that encompass feedbacks, for example, the changed vegetation itself and other properties of the land surface such as soil moisture and wetland extent, performed better than those without the feedbacks (Broström et al., 1998; Kohfeld and Harrison, 2000; [Figure 7](#)). A new generation of models

that include both land feedbacks and, importantly, ocean feedbacks, perform far better at simulating moisture Northward into the Sahara ([Braconnot et al., 2007](#)).

Northern Hemisphere Continental Aridity at 6000 ¹⁴C years BP

Wohlfahrt et al. (2004, 2008) analyzed feedbacks due to ocean and vegetation changes for the mid-Holocene as depicted in coupled ocean-atmosphere model simulations with dynamic vegetation. Their studies, which used a large biomized dataset, demonstrate how data-model comparisons using biomized data can be used to diagnose model performance. Although several large-scale features of Northern Hemisphere biome patterns corresponded well with simulations, the increase in simulated mid-continental aridity in Eurasia was not supported by the data. In this case, the atmospheric simulations alone generated xerophytic vegetation in the Asian interior, and this was enhanced by ocean feedback. The vegetation drove positive feedback towards aridity, apparently by the over-simulation of evapotranspiration. The mismatch suggests inconsistencies within those parts of models dealing with interactions between land-surface and atmosphere.

Current Developments and Future Directions

The biome approach was developed to examine continental and global vegetation patterns and as such has limitations as a tool to describe detailed vegetation history at a regional scale or smaller. It is used most successfully at these larger scales. To ensure global compatibility, taxon-PFT and PFT-biome relationships must be universally agreed, and although the method has proved remarkably successful in general, further refinements are possible. One is the incorporation of macrofossil data, which is currently an under-used paleodata resource. In Western North America, for example, where arid conditions often preclude pollen preservation, data from pack-rat middens have been used to good effect in macrofossil-based biomizations ([Thompson and Anderson, 2000](#)). Another approach, particularly promising when the focus is on paleoclimate, is to use plant traits to map vegetation. Traits can be directly selected for their bioclimatic significance, without the need to decide upon one or more PFTs for each taxon. See [Barboni et al. \(2004\)](#) for a demonstration of the utility of this approach and [Harrison et al. \(2010\)](#) for progress towards a global traits classification. Biomization has recently been combined with pollen-source theory ([Sugita, 2007](#)) to improve pollen-based estimations of treeline position ([Binney et al., 2011](#)). This approach may also be applicable to the broad-scale identification of anthropogenically modified vegetation, which is not reliably detected by the original biomization procedure.

POLLSCAPE Model: Simulation Approach for Pollen Representation of Vegetation and Land Cover

S Sugita, Institute of Ecology, Tallinn University, Tallinn, Estonia

© 2013 Elsevier B.V. All rights reserved.

Introduction

POLLSCAPE (Sugita, 1994, 1998) is a general simulation framework to explore factors and mechanisms affecting pollen deposition on mires and lakes in heterogeneous landscapes. Inter-taxonomic differences in pollen productivity and dispersal characteristics, basin size, spatial patterns of vegetation, and atmospheric conditions such as wind speed and turbulence simultaneously influence pollen dispersal and deposition (Prentice, 1985; Sugita, 1994). Simulations are a useful tool to understand functional relationships between a combination of these factors and pollen assemblages, providing us with plausible scenarios for interpreting fossil pollen data (Bunting and Middleton, 2009; Caseldine et al., 2008; Fyfe, 2006; Sugita et al., 1997). This article describes contributions of POLLSCAPE to the advances in the theory of pollen analysis and palynology, factors and mechanisms considered in POLLSCAPE, and future directions of this simulation approach.

Specifying the spatial scale of vegetation and land cover is an important step for quantitative reconstruction of past environment using fossil pollen (Davis, 2000). Traditionally, paleoecologists and palynologists have been interested in reconstructing past vegetation at a regional to subcontinental scale in order to reconstruct past climate. Pollen records from large- and medium-sized sites are appropriate for this purpose (Jacobson and Grimm, 1986; Prentice et al., 1992; Webb, 1981; Wright et al., 1994). Other ecological questions that require much finer spatiotemporal resolution, such as species invasion, stand-level vegetation dynamics, and natural and anthropogenic impacts on landscape openness, require fossil pollen records from small sites such as forest hollows (Andersen, 1970; Bradshaw and Lindbladh, 2005; Davis et al., 1998; Mitchell, 2005). Although these studies emphasized the importance of the spatial scale of vegetation represented by pollen, the source area of pollen is still ambiguous and difficult to quantify. Use of simulations in Quaternary palynology is still limited, but POLLSCAPE and related approaches have been useful in developing new concepts and methods to define the source area of pollen in complex and realistic landscapes (Sugita, 1994) and thus to reconstruct past vegetation and land cover quantitatively (Sugita, 2007a,b).

POLLSCAPE: A Simulation Framework for a Better Understanding of the Pollen–Vegetation Relationships in Vegetation with Complex Spatial Structure

POLLSCAPE was designed in such a way that pollen–vegetation relationships can be evaluated in realistic landscapes with patchy and heterogeneous vegetation (Davis and Sugita, 1997; Sugita, 1994, 1998; Sugita et al., 1997, 1999). We can gain some insights into the pollen–vegetation relationships

and pollen source area by assuming homogeneous vegetation (Davis, 1963; Prentice, 1985, 1988; Sugita, 1993). However, the spatial structure of vegetation is often complex, and pollen assemblages are expected to vary from site to site even in the same vegetation zone. There are many factors simultaneously influencing pollen dispersal and deposition at pollen sampling sites. POLLSCAPE simulations have been useful in teasing apart factors and mechanisms that most affect the pollen–vegetation relationships in this complex system.

Pollen Dispersal and Deposition Models in POLLSCAPE

POLLSCAPE simulations have used pollen dispersal and deposition models proposed by Prentice (1985, 1988), Sugita (1993), and Sugita et al. (1999). These models describe taxon-specific quantitative relationships between plant abundances surrounding pollen sites and pollen loading. Hereafter, pollen loading is defined as the number of pollen grains deposited onto the surface of bogs and lake water before sedimentation. Prentice's model estimates pollen deposition at a point at the center of a sedimentary basin and thus is appropriate for describing the relationships between plant abundance and pollen assemblages on mires and bogs, where pollen grains rarely move horizontally after deposition. Sugita's model (Sugita, 1993), modified after Prentice (1985, 1988), estimates pollen deposition on the entire surface of a basin and thus is more suitable for describing pollen loading and assemblages in lake sediment. This is because pollen originally deposited over the entire lake surface is redistributed by mixing and focusing before permanent sedimentation (Davis and Brubaker, 1973; Davis et al., 1984). Another model proposed by Sugita et al. (1999) – the Ring-Source model – provides more accurate description of pollen dispersal and deposition over the entire surface of a lake than the model proposed in Sugita (1993).

Major factors and parameters included in these three models are fall speed of pollen and pollen productivity for individual plant taxa, average wind speed, basin size and type (e.g., mire or lake), and the spatial pattern of source plants in the landscape (Figure 1). Basic assumptions of the models (Prentice, 1985; Sugita, 1993) are:

1. The sampling basin is a circular opening in the forest canopy.
2. Wind direction is even in all directions.
3. Wind above canopy is the dominant agent of pollen transport.
4. Each taxon has a constant pollen productivity in space and time.
5. Spatial distribution of source plants for each taxon is described as a function of distance from a point at the center of the basin.

Figure 1 Factors affecting pollen representation of vegetation. Modified from Sugita S and Takahara H (2001) Fourth dimension in ecology: Lessons from the past on vegetation dynamics. *Kagaku* 71: 77–85.

6. Pollen dispersal is approximated by a diffusion model of small particles from a ground-level source under neutral atmospheric condition (Sutton, 1953).

The effects on the models of departures from some of those assumptions have been examined elsewhere (Bunting and Middleton, 2005; Bunting et al., 2004; Gaillard et al., 2008; Hellman et al., 2008b; Nielsen, 2004; Sugita, 2007a,b).

These models of pollen dispersal and deposition affect how plant abundance is registered in pollen assemblages. Plants a few meters away from the basin provide more pollen grains to the sites than plants of the same abundance a few hundred meters away. At the same time, the number of plants which provide pollen to the basin increases as the distance from the basin increases. Thus, 'pollen from lakes and bogs records vegetation as a summation of plant abundance expressed in a distance-weighted fashion' (Sugita, 1998). The Prentice–Sugita model (Prentice, 1985; Sugita, 1993) and Ring-Source model (Sugita et al., 1999) describe this concept in a simple mathematical fashion (Sugita et al., 2010a). Further modification, improvement, and testing of the pollen dispersal/deposition models may be necessary, particularly because pollen dispersal distance from a point source can be sensitive to parameter selection of atmospheric conditions such as wind speed, turbulence, and heights of source plants (Bunting and Middleton, 2005; Jackson and Lyford, 1999; Sjögren et al., 2010). However, their simplicity is also a key to clarify important factors and mechanisms to approximate pollen dispersal and deposition.

On the Source Area of Pollen

Characteristic Radius

Assuming homogeneous vegetation, Prentice's (1985) model provides estimates of the area within which a given proportion of total pollen originates (e.g., 50%, 70%, or 90%) for mires and bogs of different sizes. Prentice (1988) termed the distance for the area as 'the characteristic radius' for each taxon. Sugita's models (Sugita, 1993; Sugita et al., 1999) can also be used in the same way. Figure 2 shows the characteristic radius for three different pollen types using Prentice's and Sugita's models;

(A) spruce (*Picea* spp.), (B) sugar maple (*Acer saccharum*), and (C) oak (*Quercus* spp.) (Sugita, 1993). Spruce, sugar maple, and oak produce heavy, relatively heavy, and relatively light pollen types, respectively (Prentice, 1985; Sugita, 1993). For each taxon, Figure 2 shows the changes in the characteristic radius, depending on the basin size and plant taxa. The top graph for each taxon represents predictions from Prentice's model (1985) for mires, and the bottom graph from Sugita's model (1993) for lakes. For example, when the basin radius is 50 m, 70% of spruce pollen comes from within ca. 450 m for mires and from within ca. 320 m for lakes (Figure 2a). When oak pollen accumulates, 70% comes from within ca. 12 000 m for mires and from within ca. 10 000 m for lakes (Figure 2c). The characteristic radius for sugar maple is intermediate between the two (Figure 2b). Thus, the characteristic radius varies depending on plant taxa, basin size, and basin types, and is model dependent.

The characteristic radius is a conceptually simple and useful measure to approximate the source area of pollen. However, it assumes homogeneous vegetation on a plane land surface and is not able to specify which of these source areas (e.g., 50% or 70%) is appropriate for more spatially complex vegetation patterning.

Relevant Source Area of Pollen

One of the important contributions of POLLSCAPE simulations to palynology is the concept of the 'Relevant Source Area of Pollen' (RSAP) (Sugita 1994). Based on the simulation results, the RSAP is defined as the area beyond which correlations between pollen loading and plant abundance for all taxa do not continue to improve in a given region or vegetation type (Sugita, 1994). In other words, vegetation heterogeneity within the RSAP is recorded as the variation in pollen loading among sites, superimposed on a constant background pollen loading coming from the regional vegetation. Simulation results using a hypothetical landscape with three plant taxa (Figure 3) show that pollen loading coming from beyond the RSAP (i.e., 300 m for 50-m-radius lakes in this scenario) is nearly constant for each taxon at all sites (Figure 4). Several simulations have also shown that only 30–45% of the total pollen arriving at a given site comes from within the RSAP (Sugita, 1994, 1998), which has been supported by empirical studies (e.g., Calcote, 1995). Thus, the RSAP can differ significantly from the 70% characteristic radius that is often used as a measure of the pollen source area (Prentice, 1988).

Simulations also show that the RSAP for sedimentary basins of a given size can differ between different landscapes in various regions. Several POLLSCAPE simulations (Broström et al., 2005; Bunting et al., 2004; Hellman et al., 2009a,b; Nielsen and Sugita, 2005; Sugita et al., 1999) have demonstrated that, besides the basin size, the spatial pattern of vegetation is the most dominant factor influencing the size of the RSAP. Although wind speed and atmospheric turbulence conditions strongly affect the distance of pollen dispersal from a point source (Jackson and Lyford, 1999; Sjögren et al., 2010), stronger winds and unstable atmospheric conditions would not affect the RSAP significantly (Gaillard et al., 2008; Nielsen and Sugita, 2005; Sugita, 2007a,b). Those simulation results are informative and important. More POLLSCAPE simulations

Figure 2 The characteristic radius for spruce (*Picea* spp.), sugar maple (*Acer saccharum*), and oak (*Quercus* spp.) estimated using Prentice's model (1985) for a point at the center of a basin and Sugita's model (1993) for the entire surface of a basin. Radius of a basin varies from 2 to 750 m. Red lines represent the 50% characteristic radii and green lines the 70% characteristic radii. Modified from Sugita S (1993) A model of pollen source area for an entire lake surface. *Quaternary Research* 39: 239–244.

will be necessary to elucidate important properties of the RSAP in the modern and past landscapes.

Empirically, the RSAP can be estimated using data sets of pollen percentages and vegetation abundance surrounding similarly sized sites with the Extended R-value models (Calcote, 1995; Parsons et al., 1983; Sugita, 1994). During the past decade, the number of RSAP estimates has increased in northwestern Europe, the United States, and elsewhere (Table 1). When pollen assemblages from moss polsters and forest hollows located in closed forests and dense woodlands are used, the RSAP estimates are within a 120–130-m radius in the midwest of the United States (Sugita et al., 2010b) and a 50–150-m radius in Norfolk, United Kingdom (Bunting et al., 2005). When moss polsters from semi-open forests and open landscapes are used, the estimates vary from 300 to 1000 m in radius (Broström et al., 2005; Mazier et al., 2008; Räsänen et al., 2007; von Stedingk et al., 2008). The RSAP estimates vary from a few hundred meters to 1700 m in radius when pollen assemblages from medium-sized lakes, mostly < 20–30 ha, in semi-open forests and open landscapes are used (Duffin and Bunting, 2008; Hjelle and Sugita, 2012; Nielsen and Odgaard, 2004; Nielsen and Sugita, 2005; Soepboer et al., 2007).

Other Insights from POLLSCAPE Simulations

Effects of Vegetation Patterning and Basin Size on Pollen Assemblages

POLLSCAPE simulations (Sugita, 1994) demonstrate relatively large site-to-site variation in pollen loading and pollen proportions for forest hollows and small ponds (2 and 50 m in radius) and smaller variations for larger lake sizes (250 and 750 m in radius) (Figure 5). This large variation in pollen loading for hollows and small ponds reflects the differences in plant abundance surrounding the sites in the simulated landscape (Figure 3). On the other hand, small variation in pollen loading and proportion for larger lakes, especially for lakes 750 m in radius, indicates that pollen from these lakes records the surrounding vegetation as homogeneous even when the actual vegetation is heterogeneous. 'Grain size' of vegetation heterogeneity and lake size interact, determining the efficiency with which pollen can detect local abundances of plants. Those results support the empirical observations that pollen data from smaller lakes are especially appropriate for fine-scale vegetation reconstruction, while pollen data from larger lakes are suitable for reconstruction of regional

Figure 3 Hypothetical patchy landscape simulated and used for calculating pollen deposition on a circular lake of a given radius. Some POLLSCAPE simulations use this type of patchy and heterogeneous landscapes within 60 km × 60 km or 100 km × 100 km (Sugita, 1994; Sugita et al., 1999) as well as homogeneous regional vegetation beyond the plots out to 100 to 400 km from the sedimentary basin to estimate pollen loading coming from the entire region. Three common tree taxa in the eastern United States – sugar maple (*Acer saccharum*), hemlock (*Tsuga* sp.), and yellow birch (*Betula alleghaniensis*) – are considered in this landscape. Modified from Sugita S (1994) Pollen representation of vegetation in Quaternary sediments: Theory and method in patchy vegetation. *Journal of Ecology* 82: 881–897.

vegetation and climate (Berglund, 1973; Bradshaw and Webb, 1985; Jacobson and Bradshaw, 1981; Janssen, 1972).

Factors and Mechanisms Affecting the Pollen Percentage: Vegetation Relationships

Pollen percentages are difficult to use for quantitative reconstruction of vegetation. The pollen–vegetation relationships for the same species vary from region to region because of the confounding effects of pollen percentage calculation and the differences in background pollen loading (Broström et al., 1998; Prentice and Webb, 1986; Sugita et al., 1999). For example, non-arboreal pollen percentages (NAP%) have been used to approximate landscape openness in past landscapes (Berglund, 1991; Frenzel et al., 1994). However, Broström et al. (1998) showed that the relationship between NAP% and landscape openness within 1000 m from lakes can differ significantly between southern Skåne (i.e., an open agricultural region) and northern Skåne and Småland (i.e., semi-open region) in southern Sweden (Figure 6). POLLSCAPE simulations using a similar set of open and semi-open landscape patterns (Figure 7; Sugita et al., 1999) successfully depicted the relationships that are similar to those observed in Broström et al. (1998) (Figure 6). Sugita et al. (1999) and others clearly show that the differences in both the spatial patterns of vegetation and the regional abundance of vegetation, thus background pollen loading, affect the NAP%–landscape openness relationships. It would be unrealistic to apply the modern

relationship of NAP% and landscape openness obtained from one region for reconstructing the past openness of the landscape elsewhere.

POLLSCAPE simulations have also helped understand potential and limits for the interpretation of pollen records. For example, Sugita et al. (1997) showed that pollen records would not register large-scale disturbance events (e.g., 2500 ha) even if these events occur only a few hundred meters away from study sites. This conclusion was supported in northern Finland using pollen trap data (Hicks, 1994). Data-model comparison of the pollen representation of disturbance in Estonia also supports a similar conclusion. (Kangur, 2002; Koff et al., 2000). Davis and Sugita (1997), Giesecke (2005), Poska et al. (2008), and von Stedingk and Fyfe (2009) used POLLSCAPE to demonstrate how plant migration, vegetation dynamics, and land cover changes would be recorded in fossil pollen data and to discuss implications for the interpretation of the long-term changes in spatiotemporal patterns of vegetation.

POLLSCAPE and Quantitative Reconstruction of Past Vegetation

Quantitative reconstruction of vegetation is hampered by the lack of theoretically sound methods that incorporate inter-taxonomic differences in pollen dispersal and productivity, temporal changes in background pollen, and the complex nature of pollen percentage calculations. Prentice and Parsons (1983) proposed an elegant method for quantitative reconstruction of vegetation using the inverse form of the Extended R-value models. However, unless the changes in background pollen through time are known, their method would hardly be applicable for reconstruction of vegetation and land cover.

Using POLLSCAPE, Sugita (1994) showed that pollen loading coming from beyond the RSAP in a given landscape can be estimated, once the overall regional composition of vegetation is calculated. In theory, the regional composition of vegetation and land cover can be estimated from pollen assemblages from large lakes >100–500 ha (Sugita, 1994, 1998, 2007a), because variation of pollen assemblages among those sites can be small even if vegetation is highly heterogeneous (Figure 5). This represents the first step for the Landscape Reconstruction Algorithm (LRA), a two-step framework for quantitative reconstruction of vegetation proposed in Sugita (2007a, b) (Figure 8). In the first step, the REVEALS (Regional Estimates of VEgetation Abundance from Large Sites) model, which is a generalized form of the R-value model (Davis, 1963; Parsons et al., 1983), estimates the regional vegetation composition using quantitative estimates of pollen productivity as input parameters and pollen assemblages, or counts, from large sites (Sugita, 2007a). The second step uses the LOVE (LOCAL VEgetation Estimates) model to estimate vegetation composition within the RSAP for smaller sites, subtracting the amount of pollen coming from beyond the RSAP in concept (Sugita, 2007b). Although propagation of errors in this model-based approach could potentially be problematic, LRA can overcome the problems of nonlinear relationships between pollen percentages and vegetation composition as well as the difficulties in evaluating background pollen coming from the regional vegetation (Figure 6; Sugita et al., 1999).

Figure 4 Simulated pollen loading on small ponds (radius = 50 m) using the hypothetical landscape in Figure 3. The relevant source area of pollen based on the Extended R-value model is the area within a 300-m radius from lake shore (Sugita, 1994). Pollen loading coming from within 300 m (light orange) and beyond 300 m (blue) from the shore is compared with plant cover (green) of these taxa. Modified from Sugita S (1998) Modelling pollen representation of vegetation. In: Gaillard M-J and Berglund BE (eds.) *Quantification of Land Surfaces Cleared of Forests During the Holocene – Modern Pollen/Vegetation/Landscape Relationships as an Aid to the Interpretation of Fossil Pollen Data*. Palaeoclimate Research, pp. 1–18. Stuttgart: Gustav Fischer Verlag.

Every step of the LRA approach has been evaluated and validated by POLLSCAPE simulations (Sugita, 2007a,b). In addition, Hellman et al. (2008a), Soepboer et al. (2010), Nielsen and Odgaard (2010), and Sugita et al. (2010b) have tested the LRA approach empirically.

Pollen productivity is one of the most important parameters for POLLSCAPE and the LRA applications (Figure 8). At the same time, POLLSCAPE simulations have provided important clues and insights into how to set up sampling designs to

obtain reliable estimates of pollen productivity (Broström et al., 2005; Gaillard et al., 2008). During the past decade, the number of taxa for which pollen productivity estimates are available has increased dramatically in many parts of Europe and elsewhere (Broström et al., 2008), including those in southern Sweden (Broström et al., 2004), western Norway (Hjelle, 1998; Hjelle and Sugita, 2012), Denmark (Nielsen, 2004), Great Britain (Bunting et al., 2005), northern Michigan and Wisconsin in the United States (Calcote, 1995; Sugita

Table 1 Empirical estimates of the relevant source area of pollen (RSAP) in radius currently available

Vegetation/landscape types	Pollen samples obtained from	
	Moss polsters/hollows	Lakes/reservoirs (mostly < 20–30 ha)
Closed forests/dense woodlands	Midwest, USA: 120–130 m; Sugita et al. (2010b) Norfolk, UK: 50–150 m; Bunting et al. (2005)	
Semi-open forests/open landscapes	S. Sweden: 400 m; Broström et al. (2005) C. Sweden: 500 m; von Stedingk et al. (2008) W. Switzerland: 300 m; Mazier et al. (2008) N. Finland: 1000 m; Räsänen et al. (2007)	Denmark: 1700 m; Nielsen and Sugita (2005) South Africa: 600–900 m; Duffin and Bunting (2008) Swiss Plateau: 800 m; Soepboer et al. (2007) W. Norway: 900–1000 m; Hjelle and Sugita (2012) S. Estonia: 1500–2000 m; Poska et al. (2011)

et al., 2006; Sugita et al., 2010b), the Swiss Plateau (Soepboer et al., 2007), the Swiss Jura Mountains (Mazier et al., 2008), Estonia (Poska et al., 2011), northern Finland (Räsänen et al., 2007), central Sweden (von Stedingk et al., 2008), and central South Africa (Duffin and Bunting, 2008). Currently, more studies for pollen productivity estimates are underway in other parts of Europe, central Africa, China, India, Japan, the Great Plains of the United States, northern Canada, and Australia.

Both forward modeling of POLLSCAPE and related approaches (Broström et al., 2005; Bunting and Middleton, 2005, 2009; Bunting et al., 2004; Hellman et al., 2009a,b; Nielsen and Sugita 2005; Sugita et al., 1997, 1999) and inverse modeling of the LRA (Sugita, 2007b; Sugita et al., 2010b) are important and informative for estimating the RSAP in the past landscapes, another important parameter necessary for the LOVE model (Figure 8). Although challenging, all the necessary tools are now at hand, and further POLLSCAPE and LRA

Figure 8 Landscape Reconstruction Algorithm, a two-step framework for quantitative reconstruction of vegetation and land cover. First step is to estimate regional composition of vegetation using the REVEALS model with pollen data from large lakes > 100–500 ha and estimates of pollen productivity. Pollen loading coming from beyond the relevant source area of pollen is then estimated from the REVEALS results. Second step is to reconstruct the local vegetation composition within the relevant source area of pollen using the LOVE model. POLLSCAPE simulations play an important role for estimating the relevant source area of pollen in the past landscapes. Modified from Sugita S (2007b) Theory of quantitative reconstruction of vegetation II: All you need is LOVE. *The Holocene* 17: 243–257.

experiments will be useful for robust estimates of the RSAP in various landscapes through time.

Other POLLSCAPE applications are also found at the NordForsk (Nordic Research Council) POLLANDCAL (POLLEN-LANDscape CALibration) network website (<http://www.geog.ucl.ac.uk/ecrc/pollandcal/>), coordinated by Marie-Jose Gaillard, Linnaeus University, Sweden. Members of the POLLANDCAL network have developed user-friendly packages of POLLSCAPE-related computer programs, such as OPENLAND3 (Eklöf et al., 2004), MOSAIC (Middleton and Bunting, 2004), and HUMPOL (Bunting and Middleton, 2005). These programs enable users to handle both simulated landscapes and empirical vegetation/land cover data, such as aerial photographs and digitized maps, for POLLSCAPE simulations. POLLSCAPE has become not only a useful analytical tool but also a tool to set up hypotheses and design appropriate sampling schemes specific to research objectives during project planning stages. Palynologists and paleoecologists can take full advantage of this research tool to set up a hypothesis-testing approach for a further development of the fields (Graumlich et al., 2005).

Introduction

The long-term history of human impact on vegetation – or cultural landscape history – has been a major research field within paleobotany/paleoethnobotany/archaeobotany and palynology/paleoecology in Europe since the 1960s. It is a vast topic covering a wide range of questions, approaches, and methodologies and has produced a large body of data, interpretations, and hypotheses.

Reconstruction of past cultural landscapes has traditionally been based upon the study of plant macrofossils (such as fruits, seeds, and leaves; see [Use in Environmental Archaeology](#)) and pollen grains preserved in peat and lake sediments or in cultural layers at archaeological sites. Pollen analysis has been a part of both archaeobotanical and paleoecological research. It was first applied to trace forest history and infer information on past climate. Thanks to Firbas's work on the identification of cereal pollen grains ([Firbas, 1937](#)), [Iversen \(1941\)](#) could, for the first time, identify periods of cereal cultivation in his pollen diagrams. He also could describe a typical succession of pollen assemblages ascribed to human-induced deforestation for the purpose of agriculture, known in the literature as Iversen's 'landnam' ([Figure 1](#)).

Since the publication of the 'landnam' theory by Iversen, the interest in 'human-impact' history, as inferred from 'offsite' pollen stratigraphic data (i.e., data from lake or peat stratigraphies at sites located outside the areas of archaeological findings), has increased rapidly in central and northern Europe. The anthropogenic influence on vegetation has been studied by numerous palynologists from the 1950s to the 1970s (e.g., in Sweden, [Berglund, 1969](#); [Figure 2](#)). Moreover, pollen analysis became gradually more sophisticated during the 1970s and 1980s, thanks to significant progress in the technology of microscopy and in pollen-morphological studies. Publication of increasingly detailed pollen identification keys (e.g., [Punt et al., 1976–2009](#)) greatly improved the value of pollen data for reconstruction of herb-rich, human-made vegetation, including cultivated fields, pastures, and hay meadows.

Since the 1960s, archaeobotanical research has generally included both 'onsite' (i.e., within the archaeological excavation and its findings) and 'offsite' (see above) pollen analytical investigations with the aim of reconstructing the landscape and plant environment in which humans were living and from which humans extracted food and material for building and other purposes. Pollen analytical studies within archaeobotany have mostly developed independently from 'offsite' palynological and paleoecological research on past cultural landscape (see [Use in Environmental Archaeology](#)).

In America, pollen analysis flourished as a paleoecological method, thanks to the pioneer work of Davis (see [Stand-Scale Palynology](#)), and since the 1970s, and especially the 1980s, human impact has also been studied (see review

in [McAndrews, 1988](#)). There are also very good examples of pollen analytical records of past human impact in Japan, China, the rest of Asia, and Australia (see [Huntley and Webb, 1988](#)).

This paper reviews pollen analytical methodology as a tool to reconstruct past human impact on vegetation, past land use, and past cultural landscapes with a focus on western Europe. It presents and discusses the different interpretation approaches that are used to translate pollen data in terms of human-impact and cultural landscape history.

What Questions?

Past Human Impact and Archaeology

Cultural landscape history has been a central research area within archaeology/archaeobotany. Paleobotanical questions raised by archaeologists are primarily related to the use of plants by man and to the local and regional vegetation/landscape/environment surrounding the settlement or monument. These questions might include the possible impact and consequences of different cultures and their activities on the vegetation/landscape/environment and similarly on the possible influence of the vegetation/landscape/environment on humans and their activities, and on how humans used landscapes for collection or production of food and for material to build houses, domestic utensils, etc. The types of land use (e.g., coppicing, slash and burn, pollarding, hay making, grazing, cultivation), and the spatial extent of managed areas, have also been recurrent questions. Both onsite and offsite pollen and plant macrofossil studies have been widely used in an attempt to answer these questions (see [Use in Environmental Archaeology](#)), of which many have been real challenges for pollen analysts and paleoecologists.

Past Human Impact and Climate

Attempts to separate human impact from the effects of climate change on past terrestrial ecosystems have frustrated paleoecologists. Some vegetation changes, such as shifts in forest composition, might be very difficult to ascribe to either climate change or human impact. The slow migration of *Fagus* (beech) through Europe and its late establishment in central and northwestern Europe, is a classic example of such debates (see [Stand-Scale Palynology](#)). The mid-Holocene 'elm decline' is another such example (see [Northern Europe](#)).

The possible feedback effect of human-induced deforestation on past climate changes (e.g., [Ruddiman, 2003, 2005](#)) is also an important and challenging area within climate research that has not yet been satisfactorily solved (e.g., [Gaillard et al., 2000](#)). Such questions require reliable reconstructions of the spatial distribution of human-induced open land in the past,

Figure 1 Generalized pollen diagram for a Stone Age 'landnam' with its three phases: (1) first clearance phase, decrease of tree taxa (especially elm), short-lived increase of herbaceous flora; (2) clearing by stone ax and fire, strong decrease in linden, decrease of ash and oak, and increase of anthropogenic indicators such as narrowleaf plantain, first cereal pollen; willow (*Salix*) and aspen (*Populus*) reach low maxima in the beginning, followed by peak of birch; and (3) decrease of birch and human-impact indicators, peak of hazel (*Corylus*), regeneration of elm, linden, oak, and ash. Reproduced from Iversen J (1973) *The development of Denmark's nature since the last glacial*. *Danmarks Geologiske Undersøgelse II V/7-C*: 1–26.

which is still a challenge (e.g., Gaillard et al., 2010). A major achievement of the large ESF (European Science Foundation) project 'European Paleoclimate and Man' was the evaluation of land surfaces cleared of forests during various archaeological periods (e.g., Frenzel et al., 1994). However, many of the reconstructions were based on a simple interpretation of nonarboreal pollen (NAP) percentages (Figure 3(a) and 3(b)). We now know that NAP percentage is not a reliable quantitative index of open land cover (Sugita et al., 1999, see below).

Past Human Impact and Nature Conservation

The reconstruction of cultural landscape history may also help solve questions related to nature conservation. There is an increased awareness among conservation biologists and decision-makers of the value of long-term historical information. Ecological processes operating at longer timescales must be known and understood if an ecosystem is to be maintained or restored for the future (e.g., Bradshaw and Hannon, 2004). Questions concern the need of management continuity or the necessity of a dynamic management for the maintenance of particular species or biodiversity as a whole, for instance, in herb-dominated ecosystems (e.g., Gaillard et al., 2009). The factors necessary for the maintenance of sustainable forest dynamics (such as fire and grazing) are also a subject of constant debate (e.g., Greisman and Gaillard, 2009; Olsson et al., 2010).

Approaches to Reconstruction of Past Human Impact from Pollen Data

The Indicator-Species Approach

The indicator-species approach relies on the modern ecology of species, that is, on the indicator value of species in terms of environmental characteristics such as soil properties, climate (temperature, humidity), and human-induced factors such as deforestation, cultivation, grazing, and mowing. Therefore, interpretation is based on the 'modern analog' concept, that is, the hypothesis that modern and past species' ecological requirements are comparable. In the indicator-species approach *sensu stricto*, the amount of pollen found is not critical. The presence of few pollen grains from an indicator type is the basis for interpretation. However, whether presence is scattered in time or continuous is taken into account and might lead to different conclusions on land use and human impact. Behre (1981) published a very influential paper on the use of various pollen taxa as indicators of anthropogenic vegetation types and land use (Figure 4).

The indicator-species approach and Behre's scheme of human-impact pollen indicators were used successfully by numerous European pollen analysts during the 1980s and 1990s, and were also adapted for northern Europe, for example, northern Norway (Vorren, 1986) and northern Finland (Hicks, 1992). The approach provided a way to identify variations in land-use/landscape management through time. It also made it possible to describe relative changes in the extent of total human impact and different management types. The latter may be described as a development of the indicator-species approach toward a semiquantitative reconstruction method. It was achieved by grouping and summing up the 'anthropogenic indicators' in order to obtain percentage curves of contrasting land uses (e.g., Berglund, 1991; Berglund and Ralska-Jasiewiczowa, 1986).

Anthropogenic pollen indicators

The most widely used anthropogenic indicators in pollen diagrams of northern Europe are pollen grains of cultivated crops (mainly cereals but also buckwheat (*Fagopyrum*), common flax (*Linum usitatissimum*)), narrowleaf plantain

Figure 2 Generalized human-impact diagram for the province of Skåne, southern Sweden, based on the pollen record from Lake Bjärsjöholmssjön. Major indicator pollen for (a) alder carr, (b) broad-leaved forest, (c) late migrating trees, (d) light-demanding trees, pine (*Pinus*), assumed by the author to be long-distance pollen, (e) general human-impact indicators, (f) pastures (*Plantago lanceolata* = narrowleaf plantain), and arable fields (*Cerealia* = cereals). Phases of human impact increase (expansion) 1–4 were later correlated to the following archaeological periods: (1) Early Neolithic, (2) Middle Neolithic, (3) Late Bronze Age, (4) Late Iron Age. Reproduced from Berglund BE (1969) Vegetation and human influence in South Scandinavia during Prehistoric time. In: Berglund BE (ed.) *Impact of Man on the Scandinavian Landscape During the Last Post-Glacial*, pp. 9–28 (Oikos Supplement 12).

(*Plantago lanceolata*), sage (*Artemisia*), common and garden sorrel (*Rumex acetosa/acetosella*), and heather (*Calluna*), together with pollen of the grass, sedge, and daisy families (Gramineae, Cyperaceae, and Compositae, respectively), three groups that may include species from a wide range of vegetation types, including natural, undisturbed communities. The possibility of the development of reed (*Phragmites communis*) or other shore vegetation with both grasses and sedges, concomitant to the assumed increase in human impact, should be ruled out before using these two taxa as anthropogenic indicators. Most of these anthropogenic indicators are also the most commonly found NAP in lake sediments and peat deposits of northwestern Europe, and they are often recorded in relatively high quantities. In North America, the equivalent indicators are the cultivated maize (*Zea mays*) and sage, ragweed (*Ambrosia*), sorrel, plantain and the grass, sedge, daisy, and goosefoot (Chenopodiaceae) families (see pollen diagrams and more details on the following examples in McAndrews, 1988). Pollen diagrams from ~2000-m elevation in Mexico show that human disturbance becomes evident from ca. 3.7 ka BP with the first occurrence of *Zea* together with the increase of goosefoot (*Chenopodium*) type, and the daisy and sedge families. In Guatemala, pollen diagrams are characterized from 8 uncal ka BP by low percentages of savanna trees, appearance of shrubs (Melastomataceae), increase of charcoal particles, and first occurrence of maize pollen, which may indicate that the practice of swidden (slash and burn agriculture) already occurred prior to the Maya culture. The latter displays less than 30% tree pollen. The late Preclassic, Early Classic, Late Classic, and Postclassic phases of the Maya period can often be separated by means of variations in the NAP sum. In Ontario, evidence for maize cultivation from AD 1360 consists of maize pollen together with grasses and purslane (*Portulaca*). It has been

suggested that Aboriginal farmers probably contributed to the forest succession by providing oak (*Quercus robur*) and white pine (*Pinus strobus*) with disturbed habitats necessary for seedling establishment. The peak in aspen from AD 1440 to 1570 indicates disturbance. In Connecticut, European farming started around AD 1700, which is indicated by the appearance of ragweed and sorrel pollen. Chestnut (*Castanea*) blight in AD 1913 caused a decline of chestnut pollen and a secondary succession, shown by a rise in birch followed by oak.

There are a large number of additional pollen indicators that might be identified and provide invaluable information on land use. The grouping of anthropogenic pollen taxa was used in a semiquantitative approach to draw percentage curves of human-induced vegetation types through time in several studies on past cultural landscapes. An outstanding example of this approach is found in the multidisciplinary study of the cultural landscape from 6000 BC until modern times in southern Sweden (Berglund, 1991; Figure 5). The detailed grouping used in the project (Table 1) was fully published for the first time in the first edition of the *Encyclopedia of Quaternary Sciences* (2008).

The pollen indicators are grouped into categories of human-induced vegetation as a basis for percentage calculation of groups of pollen types that can be displayed in a so-called human-impact pollen diagram (e.g., Berglund, 1991; Berglund and Ralska-Jasiewiczowa, 1986). This grouping was used within the Ystad project, southern Sweden, and is based primarily on the results of studies on modern pollen–vegetation relationships with statistical analysis and tests of those relationships (Gaillard et al., 1994; see text for more explanations). In Table 1, undifferentiated (undiff.) pollen is not identified further to group of genera (genera type) or to a single genera. It has to be stressed that many pollen types may be related to

Figure 3 NAP pollen percentages for 195 lowland sites (below 800-m altitude) at (a) 1.8 ka BP and (b) 1.45 ka BP. Lake sites are indicated by blue, mire sites by red circles. The NAP percentages were expected by the authors to ‘express the occurrence of treeless areas in some way’ and to ‘indicate regional differences.’ Sites with high NAP percentages are common in the British Isles and around the North Sea and the Atlantic seaboard for both time windows (1.8 and 1.45 ka BP). Low percentages prevail in northernmost Europe. Intermediate NAP percentages occur in North Central Europe at 1.8 ka BP while the values are low in that area at 1.45 ka BP. The authors also comment that ‘actual degree of deforestation is difficult to estimate from these maps.’ See text for more explanations. Reproduced from Frenzel B, Andersen ST, Berglund BE, and Gläser B (eds.) (1994) *Evaluation of Land Surfaces Cleared from Forests in the Roman Iron Age and the Time of Migrating Germanic Tribes Based on Regional Pollen Diagrams. Palaeoklimaforschung/Palaeoclimate Research*, vol. 12. Stuttgart: Gustav Fischer Verlag.

several of the vegetation categories and that a choice has to be made for the purpose of drawing pollen diagrams. The grouping should, therefore, be understood as one among many possible suggestions. It is the grouping that was most adequate in the south-Swedish context. Examples of pollen taxa that are relatively easy to identify with modern pollen keys (Moore

et al., 1991; Punt et al., 1976–2009) are *Ranunculus acris* type including a large number of *Ranunculus* species, several *Anemone* species (e.g., *Anemone nemorosa* and *Pulsatilla* species), *R. acris* group (*R. acris*, *R. bulbosus*, *R. repens*, and 12 other upland species), *R. ficaria* group (*R. ficaria*), *Anemone nemorosa* group (*A. apennina*, *A. nemorosa*, *A. ranunculoides*, and *A. sylvestris*),

Figure 4 The principal anthropogenic indicators in pollen diagrams and their occurrence in various farming contexts for northwestern Europe (north of the Alps). The frequency of occurrence is shown for the plants themselves and without reference to variation in pollen production and dispersal. Reproduced from Behre K-E (1981) The interpretation of anthropogenic indicators in pollen diagrams. *Pollen et Spores* 23: 225–245.

Anthriscus sylvestris type, *Chaerophyllum hirsutum* type, *Daucus carota* type, *Heracleum sphondylium* type, *Peucedanum palustre* type, *Pimpinella major* type, *Ononis* type, *Trifolium* type (in which *T. pratense*, *T. repens*, and *Medicago* spp. are not too difficult to separate), *Lotus corniculatus*, *Ulex* type (*Genista*, *Ulex*, *Cytisus*), *Vicia* type (*Vicia* spp. and *Lathyrus* spp. with possible separation of several species such as *Lathyrus pratensis*, *Vicia sylvatica*, and *Vicia cracca*), *Cichorium intybus* type (*C. intybus*, *Hieracium* spp., *Hypochaeris* spp., *Lactuca* spp., *Taraxacum* spp., and some other smaller genera), *Scorzonera humilis*, *Centaurea cyanus*, *Centaurea montana*, *Centaurea scabiosa*, *Centaurea nigra* type, *Cirsium* type, *Serratula* type, *Anthemis* type, *Cerastium fontanum* type (mainly *Cerastium* spp., *Stellaria* spp.), *Dianthus superbus* type (*Dianthus* spp., *Petrorhagia* spp.), *Sagina procumbens* type, *Scleranthus annuus* type, *Spergula arvensis* type, *Hypericum perforatum* type, and *Linum*

catharticum (see also Figures 6–14). In Figures 6–14, ‘personal observations of M.-J. Gaillard’ refer to pollen-morphological types that were not described earlier in the literature and that are based on morphological characters observed by M.-J. Gaillard.

Reliable and accurate interpretation of the occurrence of anthropogenic indicators in pollen records requires very careful identification of the pollen grains by means of detailed examination of pollen-morphological characters and a good knowledge of the ecology of the taxa. Straightforward and very precise interpretation is not always possible and may be the exception rather than the rule. The indicator value of species or groups of species may also be evaluated by means of studies of the pollen–vegetation relationship in modern analogs of past human-made vegetation types, for example, in cultivated fields, open or wooded pastures, open or wooded hay

Bjäresjösjön Pollen diagram

Figure 5 Simplified pollen diagram from Lake Bjäresjösjön (2 ha), southern Sweden. The diagram shows the groups of pollen indicators (see [Table 1](#)) used in a multidisciplinary research project on cultural landscape of the area during the past 6 ka ([Berglund, 1991](#)). The most abundant pollen taxa are presented for herbaceous plants only. The herb pollen types are dominant at Bjäresjösjön with nonarboreal pollen percentage (NAP%) of over 50% from late Bronze Age onward. General apophytes: herbaceous, terrestrial plants that are generally related to human-induced vegetation communities but cannot be ascribed to a particular land use. The record from Lake Bjäresjösjön represents the landscape around the small lake in an area of ~1000–1500-m radius. In a pollen diagram from a larger lake, Lake Krageholmssjön (220 ha), ~2 km north of Bjäresjö, NAP does not reach more than 25% until the ‘modern times’ (MoT). The contrast between these two pollen diagrams from the same area (province of Skåne, southern Sweden) is due to the size of the lakes and not to differences in the local vegetation. The record from Lake Krageholmssjön represents the vegetation of Skåne at the very large spatial scale (100 × 100 km) (see text on pollen calibration for more explanations). Reproduced from [Berglund BE \(ed.\) \(1991\) The Cultural Landscape During 6000 Years in Southern Sweden](#), vol. 41. Copenhagen: Ecological Bulletin.

meadows. This has been achieved in southern Sweden by selecting modern sites characterized by old-fashioned, traditional land use and management, collecting moss polsters in homogenous vegetation types for pollen analysis, and performing vegetation inventories (e.g., Gaillard et al., 1994). Similar studies have been performed in many parts of Europe, most recently in the Pyrenees and the Southern Alps (Court-Picon et al., 2006; Mazier et al., 2006; see Section 'The Comparative Approach').

Crop cultivation

The classical indicators for cultivation in Europe are pollen of cereals and related weeds (e.g., cornflower (*Centaurea cyanus*) and corn cockle (*Agrostemma githago*); Behre, 1981). Of these, it is only a few weeds that can be identified to species and that are restricted to cultivated fields. The cereal pollen type may include all known cultivated species within the genera wheat (*Triticum*), barley (*Hordeum*), oat (*Avena*), and rye (*Secale*), as well as wild grasses from genera such as *Glyceria*, *Elymus*, and *Bromus*. Moreover, among cereals, only the pollen of rye can be identified to species, but part of the pollen grains from rye may belong to the pollen-morphological type *Hordeum* (e.g., Andersen, 1979; Beug, 2004). Therefore, most percentage

Figure 6 Pictures of pollen grains from plant taxa indicative of human impact. All pictures were taken at magnification 1000 $\times$, except *Succisa pratensis* (400 $\times$). All pollen specimens are from the reference collection at the Paleocology Laboratory, School of Natural Sciences, Linnaeus University, Kalmar, Sweden. They were prepared from dried material collected in field from fresh plants during spring and summer, 1995 and 1996. They were embedded in glycerine jelly after acetolysis. Pictures taken by M.-J. Gaillard. Names in brackets are the pollen-morphological types according to Punt et al. (1976–2009) and Moore et al. (1991). Attribution to man-made vegetation types according to Table 1. Dry pastures, heaths, and alvar vegetation – 1, 2: *Dianthus deltoides* (*D. superbus* type) (pink family); 3–5: *Genista pilosa* (hairy greenweed) (*Genista* type) (characteristic of *Calluna* (heather) heaths, burned); 6–9: *Gentianella uliginosa* (*G. campestris* type) (gentian family).

Figure 7 Dry pastures, heaths, and alvar vegetation – 1–3: *Gypsophila fastigiata* (*G. repens* type) (southeastern European species, also occurring in 'alvar' vegetation, a particular environment on the islands of Öland and Gotland in the Baltic Sea, and in Estonia); 4–5: *Pimpinella saxifraga* (*P. major* type); 6–9: *Potentilla fruticosa* (*Potentilla* cf. *P. fruticosa*, personal observations, M.-J. Gaillard; a boreal-subalpine species in northwestern Europe are generally rare, however, common in 'alvar' vegetation) (refer to caption of Figure 6).

Figure 8 Fresh meadows and pastures – 1–3: *Veronica chamaedrys* germander speedwell (*Rhinanthus* type, *Veronica* cf. *V. chamaedrys*, personal observations, M.-J. Gaillard); 4, 5: *Vicia cracca* (tufted vetch) (*V. cracca* type); 6–9: *Cerastium arvense* (chickweed) (*C. fontanum* type) (refer to caption of Figure 6).

Figure 9 Fresh meadows and pastures – 1, 2: *Ranunculus repens* (creeping buttercup) (*R. acris* type) (*R. acris* group); 3–6: *Anthriscus sylvestris* (*A. sylvestris* type) (umbellifer family); 7–9: *Scorzonera humilis* (Viper's grass) (*S. humilis*) (characteristic of hay meadows in southern Sweden) (refer to caption of Figure 6).

Figure 10 Fresh meadows and pastures – 1–4: *Succisa pratensis* (devil's-bit scabious) (*Succisa*); 5–9: *Trifolium pratense* (meadow clover) (*Trifolium* type, cf. *T. pratense*, personal observations, M.-J. Gaillard) (refer to caption of Figure 6).

Figure 11 Fresh meadows and pastures: 1–9: *T. repens* (creeping clover) (*Trifolium* type, cf. *T. repens*, personal observations, M.-J. Gaillard). Note: the grain in the right part of pictures 1 to 5 is pollen of *Corylus avellana*. (refer to caption of Figure 6).

curves of rye in the literature might well be an underrepresentation of the species. The pollen of *Hordeum* type, *Avena* type, and *Triticum* type might include different genera and species of both wild grasses and cultivated cereals (Andersen, 1979; Beug, 2004): barley (*Hordeum*) type – *Glyceria* species, some species of *Bromus* and *Agropyron*, *Elymus arenarius* – oat (*Avena*) type – wild oat (*A. fatua*), lopsided oat (*A. strigosa*), some species of *Setaria* – wheat (*Triticum*) type – some species of *Bromus* and European beach grass (*Ammophila arenaria*).

The difficulties in matching cereal pollen-morphological types with true cultivated cereals imply that records of cereal

Viking-age landscape
in Bjäresjö, ca. AD 900

Figure 12 Reconstruction of the Viking Age landscape at Bjäresjö, southern Sweden, based upon studies in archaeology, pollen and plant macrofossil records, and agroecosystem modeling (nutrient flow systems and resource area analysis). (a) Map of the Bjäresjö area showing the possible distribution of the different land uses. (b) Artist's picture of the landscape based on the pollen diagrams and maps produced for the areas around the lakes of Bjäresjösjön (see (a) above, [Figure 5](#)) and Krageholmssjön (large lake in the background). (a) Reproduced from [Berglund BE \(ed.\) \(1991\) The Cultural Landscape During 6000 Years in Southern Sweden](#), vol. 41. Copenhagen: Ecological Bulletin. (b) Reproduced by permission of the artist Nils Forshed, Skövde, Sweden.

pollen have to be interpreted with caution and preferably in conjunction with other pollen data (findings of pollen from weeds for instance) and related paleoecological data, especially plant macrofossil records.

Slash and burn

The practice referred to as slash and burn represents a form of woodland use for agricultural purposes that are strongly associated with Nordic countries. It involved felling of trees and, after drying, setting the wood on fire and then sowing cereals

(often rye) in the clearings; in this way, the poor soils of forested areas were enriched with ash resulting from burning. After the crop was harvested, the area usually reverted to grassland and eventually woodland regenerated. In the eighteenth and nineteenth centuries, slash and burn was intensively practiced in Scandinavia, with the result that the cycle was reduced to 20 years or less, so woodlands failed to fully regenerate. In Finland, the practice coincides with the introduction of arable farming in the Neolithic period and lasted until the early twentieth century ([Vuorela, 1986](#)). In Sweden, the

Figure 13 Fresh meadows and pastures – 1–4: *Prunella vulgaris* (self-heal) (*Prunella*); 5–6: *Daucus carota* (wild carrot) (*D. carota* type) (also in dry pastures and ruderal vegetation); 7–9: *Anemone nemorosa* (*R. acris* type *A. nemorosa* group) (characteristic of wooded hay meadows; also in broad-leaved woods) (refer to caption of [Figure 6](#)).

Figure 14 Wet meadows – 1–4: *R. ficaria* (lesser celandine) (*R. acris* type *R. ficaria* group, *R. ficaria*); 5–8: *R. flammula* (lesser spearwort) (*R. acris* type *R. flammula* group) (refer to caption of [Figure 6](#)).

practice was mainly associated with spruce forests ([Lagerås, 1996, 2000](#)). It was common from the time of spruce expansion (time transgressive from northeastern to eastern and southern Scandinavia, from ca. 4 uncal. ka BP in the northeast to ca. 1 ka BP or later in the south) but ceased in the early twentieth century when it fell into disfavor because of associated fire hazards.

There are no proper pollen indicators of slash and burn, but findings of pollen from cereals (rye in particular, or oat (*Avena*) type), combined with high amounts of microscopic and macroscopic charcoal fragments in the peat or lake sediment profiles, are good indications of the occurrence of this practice in the neighborhood of the investigated site (e.g., [Lagerås, 1996, 2000](#)).

Pasture lands/grazing

Common and garden sorrel, narrowleaf and common plantain, white clover (*Trifolium repens*), prostrate knotweed (*Polygonum aviculare*), devil's-bit scabious (*Succisa*), sheep's bit/bellflower (*Jasione/Campanula*), heather, juniper, and the buttercup (*Ranunculaceae*), umbellifer (*Umbelliferae*), daisy, grass, and sedge families are all indicators of grazed areas according to the scheme of [Behre \(1981\)](#). However, they are also common in hay meadows and in ruderal (waste ground) communities around cultivated fields, on fallows, and along tracks and natural herb-rich communities (in particular,

common sorrel, narrowleaf and common plantain, white clover, prostrate knotweed, and the buttercup, umbellifer, daisy, grass, and sedge families). The specific identification of pollen from sorrels or clovers is not simple. It is not uncommon that pollen analysts do not separate species within these genera and simply present curves for the genus *Rumex* (sorrel) or the group *Rumex acetosa/acetosella* (common and garden sorrels), and for the group *Trifolium* type (*Trifolium* species and other genera and species within the clover family) or for the clover family (*Fabaceae* undiff.). Therefore, these pollen types are generally used as indicators of pasture lands and meadows, without any attempt to separate the two types of land use. Moreover, part of the pollen from these taxa may originate from contemporaneous arable fields and other human-modified environments around settlements and along tracks. Some palynologists, though, do attempt to further identify genera and species groups within the buttercup, umbellifer, clover, pink (*Caryophyllaceae*), and daisy families, and within the genera *Rumex* (sorrel), and *Trifolium* (clover), etc.; thanks to the identification keys published in [Punt et al. \(1976–2009\)](#) ([Table 1](#); [Figures 6–14](#)).

Wood pastures and forest grazing

It is not possible to confidently reconstruct the past existence of wood pastures and forest grazing (denser woods where cattle might graze and/or browse) from pollen data. This is because the representation of herbs will be overwhelmed by the dominance of tree pollen, even though they might be more common in grazed woods. Further, herbs and shrubs flower much less (produce fewer pollen grains) in wooded vegetation than in open landscapes.

However, careful examination of pollen assemblages might sometimes be interpreted in terms of wood pastures. In southern Sweden, it was proposed that a shift in pollen percentages (and pollen influx) from a dominance of broad-leaved trees such as oak (*Quercus*), ash (*Fraxinus*), elm (*Ulmus*), and linden (*Tilia*) (in mixture) to a clear dominance of birch (*Betula*) and/or oak, sometimes in connection with very slight increases in herb and/or shrub pollen, might indicate transformation of the mixed broad-leaved forests into wood pastures. Birch and/or oak trees might have been favored/preserved for the purpose of shadowing the grazing land, increasing its fodder production, and (in the case of oak) producing food (acorns) for pigs (e.g., [Lagerås, 2000](#)).

Juniper-rich pastures (the south-Swedish 'fälad') may be indicated by continuous and relatively abundant occurrences of juniper, together with significant representation of grasses, sedges, and sorrel ([Gaillard et al., 1991](#); [Figure 5](#)).

Hay meadows/mowing and the infield-outland/outfield system

As mentioned above, common sorrel, narrow-leaved and common plantain, white clover, prostrate knotweed, and the buttercup, umbellifer, daisy, grass, and sedge families are all indicators of both pastures and hay meadows. None of these taxa can be ascribed exclusively to the practice of mowing. True indicators of mowing probably do not exist, but the occurrence of certain genera or species in combination, associated with high percentages of Gramineae and narrowleaf plantain, might be a strong indication of the occurrence of hay meadows.

Examples of such pollen taxa are, for southern Scandinavia, Viper's grass (*Scorzonera humilis*) (Figure 9), yellow rattle (*Rhinanthus*), fairy flax (*Linum catharticum*), milkwort (*Polygala*), grass of Parnassus (*Parnassia*), devil's-bit scabious (*Succisa pratensis*) (Figure 10), primrose (*Primula*), and eyebright (*Euphrasia* type), which all have very specific pollen morphologies (Gaillard et al., 1994; Punt et al., 1976–2009; Table 1).

The concept of 'infield-outland system' is known in particular from the historical agrarian systems in southern Scandinavia but has many analogs in agrarian systems of Europe (Gaillard et al., 2009). It implies that arable land, together with hay meadows, are confined to the 'infields' that were separated by a fence from the surrounding 'outland' mainly used for grazing, collecting fuel, and other extensive activities. In southern Sweden, the past occurrence of the infield-outland system has been tentatively inferred from pollen data by assuming that pollen assemblages, including indicator taxa of hay meadows and cultivated cereals (often rye), also indicate the existence of infields (e.g., Gaillard et al., 1991; see Section 'The Comparative Approach'; Figure 12(a) and 12(b)).

Pollarding

Tree pollarding (i.e., pruning or cutting back upper branches of certain species of deciduous trees) has been an important element of agrarian systems in many parts of Europe. However, tracing its history on the basis of pollen data is not possible,

either using the indicator-species or the comparative approach (see also below; Gaillard et al., 1994; Figures 15 and 16).

The Comparative Approach

Parallel to the increasingly more sophisticated use of the 'indicator-species' approach, the 1980s were marked by a renewed interest in the 'comparative approach.' This involves the characterization of a range of modern vegetation types by means of contemporary pollen spectra (usually from surface samples) and then the comparison of these spectra with fossil pollen assemblages (Birks and Gordon, 1985). Until the 1990s, the use of modern pollen spectra as an aid in the reconstruction of past vegetation was rarely attempted in northwestern Europe. It was argued that the present-day flora, vegetation, and landscapes of that region were so heavily influenced by millennia of human influence that most modern pollen spectra could be expected to have little or no similarity with past fossil assemblages. Moreover, other disadvantages and limitations of the comparative approach, such as the different sources of modern pollen spectra (moss polsters, surface litter, soils, surface sediments, and pollen traps), also discouraged palynologists from applying that approach. Even though human-influenced landscapes have dominated most of the late Holocene, very few reconstructions of past vegetation/landscape units involving modern pollen spectra were attempted for vegetation types such as arable land, pasture land, or meadows.

Figure 15 Study of the pollen/vegetation/land-use relationships in southern Sweden. (a) Canonical correspondence analysis (CCA) plots (axes 1 and 2) of 124 surface pollen samples, 60 pollen and spore types, and 16 land-use and landscape variables. The position of all samples, pollen types, and several land-use/landscape variables on axes 1 and 2 is not shown. Only selected samples are shown by their scores (small signatures), and land-use variables are shown by large signatures (dichotomous variables). The plots (a) and (b) show that the land uses – grazing, mowing, and cultivation (rye or barley) – can be separated on the basis of pollen assemblages. Note that pollarding cannot be separated from mowing by means of pollen assemblages. Abbreviations: Cult, cultivation; FAL, fallow; O, oats; FL, flax; M, mowing; P, pollarding; GR, grazing. (a) CCA plot (axes 1 and 2) showing the position of modern pollen samples from 44 grazed and 24 mowed or mowed and pollarded sites in relation to the scores for the grazing, mowing, and pollarding variables. (b) CCA plot (axes 1 and 2) showing the position of modern pollen samples from 11 cultivated sites (16 pollen spectra) with different crops in relation to the scores for the variables crop cultivation, rye, barley, oat, and flax cultivation, and fallow. The scores for the land-use variables (large signatures) are represented by their centroid or weighted average of the site scores (small signatures) where the variable is present. The dashed line delimits the distribution of individual mowed or mowed and pollarded sites. Reproduced from Gaillard MJ, Birks HJB, Emanuelsson U, Karlsson S, Lagerås P, and Olausson D (1994) Application of modern pollen/land-use relationships to the interpretation of pollen diagrams – Reconstructions of land-use history in south Sweden, 3000–0 BP. *Review of Palaeobotany and Palynology* 82: 47–73.

Figure 16 Plot of the 66 fossil pollen samples (black dots) (Lake Bjäresjösjön) positioned as 'passive' samples on CCA axes 1 and 2 of **Figure 15**. Biplot arrows and centroids for 12 selected land-use/landscape variables are shown. Clusters of sample scores (a–g) have been delimited by eye and are joined up in stratigraphical order. Cluster D is subdivided into three subclusters (dotted lines). The dotted area represents the distribution of the scores for mowed or mowed and pollarded sites (see **Figure 15**). Abbreviations: M, mowing; P, pollarding; Fal., fallow; Cult., cultivation. Reproduced from Gaillard MJ, Birks HJB, Emanuelsson U, Karlsson S, Lagerås P, and Olausson D (1994) Application of modern pollen/land-use relationships to the interpretation of pollen diagrams – Reconstructions of land-use history in south Sweden, 3000–0 BP. *Review of Palaeobotany and Palynology* 82: 47–73.

The first attempt at using the comparative approach for human-influenced vegetation in Europe was published by Berglund and Ralska-Jasiewiczowa (1986). Pollen in moss polsters from modern analogs of ancient, nonfertilized grazed and mowed plant communities was used to explore whether these land uses could be separated by means of pollen assemblages. This pioneer work was followed by a series of studies on the pollen/vegetation/land-use relationships in modern analogs of ancient cultural landscapes in southern Sweden (Gaillard et al., 1994, 1998). This resulted in a large database of 120 pollen assemblages and related vegetation, land-use, and other environmental variables such as soil chemistry, from human-influenced sites. One of the most interesting results of this research was the ability to separate hay meadows from grazed pastures by means of pollen assemblages (**Figure 15(a)** and **15(b)**). The use of the comparative approach on a fossil profile from southern Sweden revealed that pollen assemblages dating from the pre-Roman Age up to the Vendel Period (500 BC–AD 800) were significantly similar to the modern pollen assemblages from traditional, nonfertilized hay meadows (**Figure 16**). This was the first convincing independent demonstration of the early occurrence of species-rich meadows comparable to traditionally managed hay meadows. The modern analog and comparative approaches were later adopted by several scientists in Europe, first in Finland, Norway, and Denmark during the 1990s (e.g., Hicks and Birks, 1996) and recently in the French

Pyrenees (Mazier et al., 2006, 2009; **Figures 17** and **18**), and in southern France (Court-Picon et al., 2006).

Calibration of Pollen Data onto Land Cover

Quantification of the human-induced landscape openness in absolute plant abundance values, such as percentage cover, has been an important challenge for palynologists. It has been a research focus in southern Sweden for more than 10 years (e.g., Broström et al., 2004; Gaillard et al., 1998, 2000, 2010; Hellman et al., 2008; Sugita et al., 1999). Pollen assemblages from lake-surface sediments were related to the percentage cover of major landscape units for 40 sites within traditional cultural landscapes in the hope of establishing calibration functions that would allow reconstruction of human-induced landscapes in terms of absolute coverage of vegetation/landscape units such as wooded versus open land, pastureland, cultivated land, etc. Broström et al. (1998) presented empirical data demonstrating that the sum of NAP was not linearly related to open land cover within a 1000-m radius around the pollen sampling point, if pollen samples were from contrasting vegetation regions. Sugita et al. (1999) used a simulation approach involving models of pollen dispersal and deposition (see **POLLSCAPE Model: Simulation Approach for Pollen Representation of Vegetation and Land Cover**) to test the ability of NAP to represent open land. The results showed that NAP percentages cannot be used as a straightforward measure of landscape openness because the share of NAP depends on the proportion and taxa composition of the background pollen component in the pollen assemblage (**Figure 19(A)** and **19(B)**). A different approach than the traditional 'transfer function' methodology needed to be applied in order to tackle this problem. Sugita (2007a,b) proposed the Landscape Reconstruction Algorithm (LRA) approach. It implies estimation of the background term in the equation of the pollen–vegetation relationship according to extended *R*-value (ERV) models (see **POLLSCAPE Model: Simulation Approach for Pollen Representation of Vegetation and Land Cover**). The LRA includes two models, Regional Estimates of Vegetation Abundance from Large Sites (REVEALS) that calculates regional vegetation abundance (RVA, spatial scale 100 × 100 km) using pollen data from large sites (lakes or bogs, ≥100 ha) and the Local Vegetation Estimates (LOVE) model that infers local vegetation abundance within the relevant source area of pollen (RSAP) of the study site (*sensu* Sugita, 1994, ≤100 km² area) using pollen records from small sites (≤10 ha). LOVE uses the REVEALS estimates to calculate the background pollen for small sites and also estimates the RSAP; it then can calculate the local plant abundance within the RSAP (see **POLLSCAPE Model: Simulation Approach for Pollen Representation of Vegetation and Land Cover**). Reliable estimates of pollen productivity estimates (PPEs) are required for application of the LRA (e.g., Broström et al., 2004, 2008). The number of plant taxa for which PPEs are available has rapidly increased in many parts of northern Europe (Broström et al., 2008).

The REVEALS model is now validated in southern Sweden (**Figures 20** and **21**; Hellman et al., 2008) and the Swiss Plateau (Soepboer et al., 2010), and the LOVE model in Michigan and Wisconsin (Sugita et al., 2010) and southern Sweden (Fredh et al. and Cui et al. in progress). The excellent performance of REVEALS to predict the regional coverage of

Figure 17 Study of modern pollen assemblages from grazed vegetation in the Western Pyrenean Mountains (France). Redundancy analysis (RDA) of the modern pollen assemblages using 13 explanatory variables (nominal variables are given with their centroids (solid circles) and quantitative variables with solid arrows), four passive variables (italic), and selected taxa (dotted arrows). (a) Taxa scores and environmental variables on RDA axes 1 and 2. (b) Taxa scores and environmental variables on RDA axes 1 and 3. The three first axes explain, respectively, 17.9, 6.2, and 5.4% of the total variation in the modern pollen data and are all significant ($P < 0.001$ after 999 permutations). LOI, loss on ignition. Abbreviations of selected taxa: Art, *Artemisia* (sage); Ast, *Asteraceae* (daisy family); Cal, *Calluna* (heather); Che, *Chenopodiaceae* (goosefoot family); Cic, *Cichoriaceae* (daisy family); Cir-typ, *Cirsium* (thistle) type; Fag, *Fagus* (beech); Gal, *Galium* (bedstraw) type; Poa, *Poaceae* (grass family); Pla, *Plantago* (plantain); Pla-lan, *Plantago lanceolata* (narrowleaf plantain); Pla-med, *Plantago major/media* (common plantain); Pin, *Pinus* (pine); Que-tot: *Quercus* (oak) total, Pot-typ: *Potentilla* (cinquefoil) type; Ran, *Ranunculaceae* (buttercup family); Rub, *Rubiaceae* (madder family); Rum, *Rumex* (sorrel); Rum-ace, *Rumex acetosa/acetosella* (garden sorrel/common sorrel); Rum-obt, *Rumex obtusifolius*; Ste-typ, *Stellaria* type; Urt-dio, *Urtica dioica* (nettle). Reproduced from Mazier F, Galop D, Gaillard MJ, et al. (2009) Multidisciplinary approach to reconstructing local pastoral activities: An example from the Pyrenean Mountains (Pays Basque). *The Holocene* 19: 171–188.

Figure 18 Application of the comparative approach in the Western Pyrenean Mountains (France), as an aid to the interpretation of Holocene pollen assemblages in terms of land use. Plot of 27 fossil pollen samples from the Holocene pollen record of Sourzay (open diamonds) positioned as 'passive' samples on the RDA axes (see Figure 17) with explanatory variables (nominal variables are given with their centroids (solid circles) and quantitative variables with solid arrows) and four passive variables (italic). Numbers (e.g., S53) correspond to the depth of the samples. (a) Fossil samples and environmental variables on RDA axes 1 and 2. (b) Fossil samples and environmental variables on RDA axes 1 and 3. Fossil samples are projected onto the arrow of the grazing pressure variable to provide a relative degree of grazing pressure. Clusters of sample scores (1–4) have been delimited by eye and are numbered in stratigraphical order. Tentative interpretation: Cluster 1: open wet pastureland on rich soils; relatively low pastoral activities. Two major vegetation types: grazed wet vegetation and encroached heathland. Cluster 2: increase in grazing pressure and colonization by trees. From sample 21, there is an indication of a mixture of more or less wooded vegetation with grazing and trampling activities and variable grazing pressure. Note the shift S27–S29–S31 between clusters 2 and 3. Cluster 3: forested phase with little pastoral activity rather rich soils and varying grazing and trampling activities. Cluster 4: open pasture, mosaic landscape with heathland communities, fern fallow, overgrown lawn, and semi-open beech forest; poor soils, and grazing and trampling activities. These different land-use phases were compared with archaeological studies in the area. Reproduced from Mazier F, Galop D, Gaillard MJ, et al. (2009) Multidisciplinary approach to reconstructing local pastoral activities: an example from the Pyrenean Mountains (Pays Basque). *The Holocene* 19: 171–188.

Figure 19 Comparison of the nonarboreal pollen (NAP)/open land relationship in two areas of southern Sweden (the Skåne and Småland provinces) based on empirical and simulated data (see text for explanations). (A) Hypothetical landscapes used for simulations. (a) Open landscape mimicking the open, agricultural landscape in southern Skåne, with a matrix of open land (cultivated fields, meadows, and pastures) and scattered patches of woodland types. (b) Semi-open landscape mimicking the semi-open, forested landscape of northern Skåne and Småland with a matrix of spruce and scattered patches of open land (cultivated fields, meadows, and pastures) and different woodland types. (B) Scatter plots of NAP percentage in surface sediments from small lakes versus percentage cover of open land within 1000 m of the lakes. (a) Empirical relationships between NAP percentages versus percentage cover of open land in southern Skåne (diamonds, Gaillard et al., 1998) and in northern Skåne and Småland (crosses, Broström et al., 1998). (b) Simulated relationships between NAP percentage versus percentage cover of open land within 1000 m of 3.14-ha lakes using the hypothetical landscapes of (A) and models of pollen dispersal and deposition. Three landscape designs with different degrees of openness, that is, 30% (stars), 60% (triangles), and 90% (squares), were used for simulation. The empirical data for Skåne are very similar to the simulation data for a landscape for a regional openness of 90%, while the empirical data for Småland are comparable to the simulation data for a regional openness of 30%. Reproduced from Sugita S, Gaillard MJ, and Broström A (1999) Landscape openness and pollen records: A simulation approach. *The Holocene* 9: 409–421.

vegetation/landscape units such as open versus wooded land, conifer forests, broad-leaved woods, cereal fields, and even individual tree, shrub, and herb taxa (Figure 21) represents a new and exciting potential in the use of pollen analysis for the reconstruction of past landscapes in quantitative terms, that is, past coverage of various plant groups or individual taxa and species, for example, human-induced vegetation types or forested versus open vegetation. Similarly, the LOVE model offers the potential to estimate plant cover at the spatial scale of small sites RSAP, which may help to answer specific questions that traditional interpretation of pollen data cannot solve, for

example, questions on the size of human-induced vegetation/landscape units such as cultivated and grazing land or the share of tree taxa in forested vegetation.

Applications of the LRA, REVEALS, and LOVE Models

The first REVEALS-based reconstructions of Holocene vegetation in southern Sweden indicate that human impact on land cover over the last 3000 years, as well as landscape openness during early Holocene (11500–10000 cal years BP), was much more profound than changes in pollen percentages

Figure 20 Validation of Sugita's REVEALS model in southern Sweden (see text for explanations). REVEALS estimates of regional vegetation abundance compared (a) with percentage coverage in the present vegetation and (b) with pollen percentages, for the following taxa groups: total trees (vegetation: Skåne – dark blue, Småland – red; pollen: Skåne – light blue, Småland – purple), total herbs (vegetation: Skåne – yellow, Småland – sand; pollen: Skåne – red brown, Småland – orange), sum conifers (vegetation: Skåne – light blue, Småland – brown; pollen: Skåne – green, Småland – dark green), and sum broad-leaved trees (vegetation: Skåne – light green, Småland – pink; pollen: Skåne – dark blue, Småland – light green). Reproduced from Hellman S, Gaillard M-J, Broström A, and Sugita S (2008) Pollen in large REVEALS regional plant abundance – Model validation in southern Sweden and potential for reconstruction of past vegetation abundance and land cover, *Journal of Quaternary Science* 22: 1–22.

Figure 21 Vegetation proportions predicted by REVEALS (left) and pollen proportions from lake-surface pollen assemblages (right) plotted against vegetation proportions compiled from various sources of vegetation data with their respective error estimates, for (a) abundant taxa (>2%) and (b) rare taxa (<=2%) in Skåne (A, Trees; B, Herbs) and in Småland (C, Trees; D, Herbs) (see caption of Figure 20). Tree taxa: alder (light green), birch (dark blue), hazel (dark red), beech (light red), spruce (dark brown), and pine (light brown), maple (dark green), hornbeam (light blue), ash (dark pink), juniper (light orange), oak (dark purple), willow ssp. (light purple), linden (orange), and elm (light yellow). Abundant herb taxa (Ba, Da): cereals (dark red), daisy family (light red), grasses (light blue), and rye (orange). Rare herb taxa (Bb, Db): heather (dark purple), sedges (blue), *Filipendula ulmaria* (meadowsweet) (pink), narrowleaf plantain (dark green), cinquefoil (yellow), *Ranunculus acris* (meadow buttercup) (light green), madder family (dark brown), and garden sorrel type (light brown). Reproduced from Hellman S, Gaillard M-J, Broström A, and Sugita S (2008) Pollen in large lakes REVEALS regional plant abundance – Model validation in southern Sweden and potential for reconstruction of past vegetation abundance and land cover. *Journal of Quaternary Science* 22: 1–22.

Figure 21 (Continued)

Figure 21 (Continued)

Figure 22 REVEALS estimates of plant groups through the Holocene in southern Sweden. REVEALS reconstructions of Holocene vegetation changes (right in each panel) in southern Sweden based on the pollen records (left in each panel) from Krageholmssjön (province of Skåne, left) and Lake Trummen (province of Småland, right). REVEALS was run with the PPEs from southern Sweden (Broström et al., 2004). Conifers = *Pinus* (pine), *Picea* (spruce), *Juniperus* (juniper); Deciduous trees = *Alnus* (alder), *Betula* (birch), *Corylus* (hazel), *Quercus* (oak), *Ulmus* (elm), *Tilia* (linden), *Fraxinus* (ash), *Fagus* (beech), *Carpinus* (hornbeam), *Salix* (willows); Cerealia-t = cereals; rye excluded; other nonarboreal plants = *Calluna* (heather), Compositae subfamily Cichorioideae (lettuce, dandelions, and others), Cyperaceae (sedges), *Rumex acetosa*-t (sorrels, in particular common sorrel and sheep's sorrel), *Filipendula* (meadowsweet), *Ranunculus acris* (buttercup), *Plantago lanceolata* (narrowleaf plantain); *Secale* = rye; Poaceae = grasses. Reproduced from Gaillard MJ, Sugita S, Mazier F, et al. (2010) Holocene land-cover reconstructions for studies on land cover-climate feedbacks. *Climate of the Past* 6: 483–499.

alone would suggest (Sugita et al., 2008). The cover of open land through the Holocene is shown to be strongly underestimated by percentages of NAP. For instance, at the regional spatial scale, openness estimated by REVEALS for the last 3000 years reached 50–80% in Skåne and 20–40% in Småland (compared to 20–40% and 3–10% NAP, respectively; Figure 22). A REVEALS reconstruction of the regional vegetation of the Swiss Plateau for the past 2000 years also showed that anthropogenic impact is underestimated by NAP (Soepboer et al., 2010). Therefore, spatial structure and openness of vegetation caused by both natural and anthropogenic disturbances over the last 10 000 years may have been more substantial than earlier assumed. Within an ongoing Swedish project, LANDCLIM, REVEALS is applied to estimate land cover during the Holocene in northwest Europe and western Europe north of the Alps for the purpose of climate and dynamic vegetation model evaluation (Figure 23; Gaillard et al., 2010). These REVEALS vegetation reconstructions confirm that landscape openness in the study region was already

significant from 3000 cal years BP or earlier and that the cover of treeless vegetation was larger than NAP percentages suggested. The latter has important implications for a number of paleoecological issues, such as the land cover-climate feedbacks through time. For instance, these REVEALS estimates of open land cover in Europe support the picture proposed by Kaplan et al. (2009). His scenarios of anthropogenic land cover change based on a different modeling approach also suggest a much more open landscape in Europe during the late Holocene than earlier assumed (Gaillard et al., 2010).

The first published LRA application was performed using nine late Holocene (the last 3000 years) pollen records from the major landscapes characteristic of Denmark (Nielsen and Odgaard, 2010; Figure 24). The LOVE estimates of plant cover within the RSAP of the nine sites showed that the Danish landscapes were heavily influenced by pastoral activities throughout the studied period, resulting in a dominance of grassland (40–90%) on fertile soils and a mixture of grass (40–80%) and heather (*Calluna*) (10–60%) heathlands on

Figure 23 Example of REVEALS estimates produced by the LANDCLIM project for the time windows 6000, 3000, and 200 cal years BP (present = 1950), first generation LANDCLIM maps (produced by Anna-Kari Trondman, Florence Mazier, Anne Birgitte Nielsen, Ralph Fyfe and LANDCLIM members for the purpose of this article; see Gaillard et al. (2010) for a description of the LANDCLIM project): PFT agricultural land (AL = cereals total (*Cerealia* undiff., *Triticum* (wheat) type, *Avena* (oats) type, *Hordeum* (barley) type, *Secale cereale* (rye)) and PFT grassland (GL = *Cyperaceae*, *Filipendula*, *Plantago lanceolata*, *Plantago montana*, *Plantago media*, *Poaceae*, *Rumex* p.p. (mainly *R. acetosa* and *R. acetosella*, i.e., *Rumex acetosa* pollen-morphological type). The first generation of LANDCLIM REVEALS estimates is based on all available Holocene pollen records ($n=420$) from small and large sites (lakes and bogs) including all or part of the time windows 6000, 3000, 600, 200, and 0 cal years BP (1950), and with ≥ 3 dates for the chronological control. These pollen records were collected from the European (EPD), Alpine (ALPADABA), and Czech (PALYCZ) pollen databases (Fyfe et al., 2007; van der Knaap et al., 2000; Kunes et al., 2009, respectively). The PPEs are, for each taxon, the mean of all PPEs obtained within the project area (northwestern Europe and western Europe north of the Alps, Broström et al., 2008). These maps clearly show the strong increase in size of the land surfaces covered by agricultural land (here exclusively cultivated with cereals) and by grassland (here mainly grasses) between 6000 BP (Neolithic) and 3000 BP (Late Bronze Age), and between 3000 and 200 BP (AD 1750–1800).

Figure 24 LRA reconstructions of the openland cover during the last 3000 years at two contrasting sites of Denmark, (a) Gudme sø (eastern Denmark) and (b) Skaansø (western Denmark). Reproduced from [Nielsen AB and Odgaard BV \(2010\)](#) Quantitative landscape dynamics in Denmark through the last three millennia based on the Landscape Reconstruction Algorithm approach. *Vegetation History and Archaeobotany* 19: 375–387 (see text for more explanations on LRA). Simplified pollen percentage diagram for major trees and herbs and LRA–LOVE reconstruction for total trees, grasses, *Calluna* (heather), and *Cerealia*. The LOVE reconstructions clearly show that pollen percentages of cereals and grasses underrepresent the cover of these plants in the vegetation. At Gudme sø, grasses cover ~50–80% of the landscape through the studied period, and in Skaansø, ~40–80%. The cover of agricultural land increases at both sites from ca. AD 100 and maintains values of ~10% from AD 1000 at Gudme sø, while they are slightly lower at Skaansø where heathlands (15–60% cover of *Calluna*) represent a large part of the landscape.

sandy soils. It is clear from this study that the degree of openness of the landscape during the last 3000 years was much higher than suggested by the uncorrected pollen percentages (10–<40% grasses and ≤30% *Calluna*). A LOVE vegetation reconstruction at two localities in southern Sweden (partly published in Marlon et al. (2010) was the only means to show that pine was more abundant at one site than at the other, which explained a significant difference between the two sites in terms of fire history, fire activity being highest at the pine-rich site during middle and late Holocene (Marlon et al., 2010; Figure 25).

Conclusions and Prospects

Pollen analysts and paleoecologists have made enormous progress in the interpretation of pollen in terms of precise vegetation abundance and landscape character. The

development of models of the pollen–vegetation relationship including pollen dispersal and deposition models (e.g., Prentice and Parsons, 1983; Sugita, 1994) led to a better understanding of the vegetation quantitative composition and spatial scale represented by pollen percentage assemblages. The computer simulation program POLLSCAPE (Sugita, 1994) and its successor HUMPOL (Bunting and Middleton, 2005) allow us to simulate pollen percentages in basins (bogs or lakes) of different sizes in hypothetical or real landscapes. It provides a means of testing the effect of changing various parameters on pollen percentages, that is, insights on the pollen representation of vegetation (see POLLSCAPE Model: Simulation Approach for Pollen Representation of Vegetation and Land Cover). The LRA (Sugita, 2007a; Sugita, 2007b), with its two models REVEALS and LOVE, is very useful complements to the traditional indicator and comparative approaches, and they are the most sensible methods so far to estimate vegetation abundance in absolute terms (for instance,

Figure 25 LRA reconstruction of 20 tree and herb taxa at two sites of southern Sweden, Stavsåkra (STAV) and Storasjö (SSJ) (see Olsson et al., 2010 for details on these sites and their fire history; modified from Marlon JF, Cui Q, Gaillard MJ, McWethy D and Walsh M (2010) Humans and fire: Consequences of anthropogenic burning during the past 2 ka. *Pages News* 18: 80–82); only four taxa are shown here, *Pinus* (pine), *Betula* (birch), *Corylus* (hazel), and *Calluna* (heather). The LOVE estimates are shown with their standard errors (blue dashed lines for Stavsåkra, red dashed lines for Storasjö). RSAP = Relevant source area of pollen, i.e., smallest radius of the area for which the reconstruction of plant abundance in % cover is valid (see Sugita, 1994). In this case it varies between 500 and 2500 m radius throughout the Holocene. The RSAP is mostly influenced by the structure of the vegetation (Hellman et al., 2009a,b). The LOVE estimates of *Pinus* and *Betula* show clear differences in species composition of the forests at the two sites, that is, up to 40% cover of *Pinus* and very low values of *Betula* except at the beginning of the Holocene at Storasjö and up to 60% cover of *Betula* and very low values of *Pinus* at Stavsåkra. The charcoal records are presented for comparison. The relatively high fire activity at Storasjö compared to Stavsåkra during the mid-Holocene might be due to the continuous presence of pine in high abundance at Storasjö during the entire Holocene, while Stavsåkra was characterized by a dominance of broad-leaved trees in the close vicinity of the site. This between-site difference in forest composition was not clearly shown by the pollen percentages or the pollen accumulation rates (e.g., Greisman and Gaillard, 2009), which illustrates the importance of using pollen–vegetation modeling for questions of this kind.

in percentage cover or in ha within a defined area). The challenges are now to (1) further evaluate the performance of REVEALS and LOVE in other landscapes than southern Sweden, Denmark, and North America; (2) gather all data necessary for the acquisition of the model parameters, PPEs, and FSP (fall speed of pollen), in other regions of the world; and (3) develop adequate methods to improve the production of landscape maps at regional and local spatial scales. The latter might be found in the use of GISs (geographical information systems) and related modeling, and in spatial modeling statistics.

DEDICATIONS

The second edition of the Encyclopedia of Quaternary Science is dedicated to the memory of three outstanding scientists who have recently passed away: Russell Coope, Bill Watts, and Aleksis Dreimanis.

Russell Coope

G. Russell Coope (1930–2011) was essentially the founding father of Quaternary Entomology, having initiated the modern era of Quaternary insect fossil research in the late 1950s. Prior to that time, and going back to the nineteenth century, there had been a number of false starts and stops in this field. Previous researchers had assumed that any ice-age insect fossils they found would necessarily represent extinct taxa. This, as it turns out, was a completely false assumption. Beginning with the Late Pleistocene Upton Warren and Chelford sites, Russell was able to determine that fossil insects, especially beetles (Coleoptera) from Pleistocene deposits, represent extant species, albeit species that may live in dramatically different regions today than those where they lived in the past. For many years at the start of this endeavor, Russell was ‘a voice in the wilderness,’ having to convince colleagues in both the Quaternary sciences and modern Entomology that it is possible to identify ‘beetle bits’ (individual sclerites of beetle exoskeleton) to the species level, and that fossil beetle assemblages can yield reliable reconstructions of past environments. One of his greatest battles was to convince skeptical palynologists that the interstadial interval in what is now known as MIS 3, and another one toward the end of the last glaciation, were almost as warm as today, in spite of the fact that the vegetation cover represented in pollen records failed to register this. Likewise, Russell championed the idea that climate oscillations, particularly in the late glacial interval and early Holocene, were extremely rapid and dramatic: switching from full glacial to full interglacial conditions in a matter of decades, at most. Russell’s paleoclimate reconstructions were finally given full credence by the scientific community at large when the oxygen isotope records from Greenland ice cores began to be published, showing nearly the exact same amplitude and timing of climate change he had been publishing since the 1960s.

Russell’s research has had important implications for the field of zoogeography. On the basis of his work, we now know that insects respond to climate change chiefly by shifting their distributional ranges, so that they

Figure 1 Russell Coope at the Chelford quarry fossil site, August 1977. Photograph by Alan V. Morgan, used with permission.

track these changes through space. Through his tenacity and hard work, Russell was able to track down the modern ranges of beetle species he found in Pleistocene deposits to such remote locations as northeastern Siberia and the Tibetan Plateau (cold-adapted species), as well as North Africa and the Mediterranean islands (warm-adapted species).

Russell brought a level of curiosity and enthusiasm for natural history and all things scientific that was infectious. He was a brilliant lecturer and storyteller, holding his audiences practically spellbound. He trained many of the paleoentomologists who took the field forward in recent decades. His seemingly boundless energy kept him working and publishing papers, right up to the end of his life. He published more than 200 papers in his long career. He collaborated with dozens of other Quaternary scientists and was one of the first to appreciate and promote multidisciplinary studies of Pleistocene fossil sites. There is no doubt that his research and publishing legacies will continue to inspire future generations of paleoentomologists.

Bill Watts

William (Bill) A. Watts (1930–2010) was a towering figure in Quaternary paleoecology. He was a skilled botanist and ecologist and this was a secret to his success in unraveling the interglacial, late-glacial, and Holocene vegetation history not only in his native Ireland but also in the midwestern, the southeastern, and eastern USA, and in Italy. A major contribution was his reintroduction and development of quantitative plant macrofossil analysis. Macrofossils can often be identified to lower taxonomic levels than pollen, and Bill took full advantage of the complementarity of both methods. Thus, he was able to determine important features of vegetation history by identifying trees to species level and to illuminate the history of aquatic plants and local vegetational developments.

Figure 2 Photograph of Bill Watts, taken at Laguna de la Roya, Spain. Photograph by Fraser Mitchell, used with permission.

Bill always enjoyed fieldwork and microscope work, carrying out the latter in spare time left over from his job as Provost of Trinity College Dublin and his participation on committees dealing with hospitals and conservation in Ireland. Bill's quiet but intense enthusiasm and his great sense of humor added much to discussions, macrofossil identification sessions, and excursions with him. He and his work are inspirations to those who follow him.

Figure 3 Aleksis Dreimanis, photograph by Stephen Hicock.

Aleksis Dreimanis

Aleksis Dreimanis (1914–2011) was widely considered the world's foremost Quaternary glacial geologist in the 1970s and 80s. Aleksis was born in Latvia. While still an undergraduate at the University of Latvia, he published his first paper on the structural geology of deformed glacial deposits along the banks of the River Daugava – a study that he would return to and revise 60 years later. In 1944, Aleksis was conscripted as a military geologist by the Germans who occupied Latvia. For the next two years, he was separated from his family and forced to do strategic geological mapping in eastern Germany and northern Italy until the end of WWII, followed by internment in prisoner of war and displaced persons camps. In 1948, he escaped to London, England, where he met with the President of the University of Western Ontario who gave him a job in London, Canada (his family was able to join him the following year).

Over the next six decades at the University of Western Ontario, Aleksis ascended to the top of his discipline while gaining international recognition through landmark publications and inspired leadership on committees. His 1970s synthesis and definition of the Wisconsin Stage with Paul Karrow, Jan Terasmae, Dick Goldthwait, and Jane Forsyth became a world standard to which other records were compared. In 1989, he expanded this synthesis and introduced the conceptual till tetrahedron that showed the till continuum with end members occupying the corners of an inverted pyramid. He was among the first geologists to use radiocarbon dating, and he provided samples for inter-lab calibration. He was among the first to quantitatively study the relationship between till lithology and till formation, and to investigate how glacial transport and dynamics determine till texture, deformation, and rheologic states. Aleksis produced over 200 publications spanning eight decades and over a wide range of topics. Largely because of his influence, the study of till genesis and its relation to till properties and past glacial behavior has become a major focus of glacial geologic research in recent decades. The contribution and legacy that forms the body of work of Dreimanis will continue as a major benchmark within the diverse fields of scientific enquiry that are sometimes loosely referred to as 'glacial geology.'

FOREWORD

As with the publication of the first edition in 2007, the publication of the second edition of the *Encyclopedia of Quaternary Science* represents a landmark in the history of publishing in the field of Quaternary Science. Quaternary Science is a multidisciplinary endeavor which seeks to establish as detailed a picture as possible of the manifold environmental changes that have occurred during the most recent geological period, the Quaternary – an interval of time that spans the past 2.59 million years or the past 0.056% of geological time. It is a period of significant climate and environmental change and witnessed the widespread dispersal of our species, *Homo sapiens*, across the planet.

Since Louis Agassiz and Reverend William Buckland traipsed over parts of the Scottish landscape in 1840 in search of evidence of glaciation, a huge literature has emerged on the science of long-term climate and environmental change. Rapid technological advances in the late twentieth century and the proliferation of scientific journals, particularly in an era of electronic publishing, have resulted in an exponential growth and documentation of knowledge on the climate and environmental changes that have occurred during the Quaternary period. More recently, there has been an increasing public interest in applied Quaternary research as a framework for understanding the basis for recent climate changes and for understanding the nature and frequency of geological hazards and vexing issues such as soil erosion and land degradation, and the adverse effects of ocean water temperature increases and acidification on coral reef environments. In a similar manner, the likely magnitude of future sea-level rise and the associated impacts on coastal landscapes in the twenty-first century have attracted wide public interest. In this sense, Quaternary Science is very much on the political agenda and is a critically important subject to address issues of public concern.

The *Encyclopedia of Quaternary Science* edited by Scott Elias of Royal Holloway, University of London, UK, accordingly represents a particularly welcome addition to the literature. The encyclopedia presents an up-to-date and authoritative overview of Quaternary Science. The encyclopedia should enjoy a wide readership as the entries are presented in a very clear and easily readable style. The text of the articles is written at a level that allows undergraduate students to understand the material, while providing active researchers with a ready reference resource for information in the field. Each entry of up to 4000 words covers the salient points of each topic with very clear illustrations. A central theme that pervades the work is the importance of Quaternary Science in providing an historical context for assessing present environmental changes and as basis for modeling potential future changes.

The encyclopedia consists of four volumes in print form and is available electronically. All the entries have been updated and the text totals around 3,500,000 words. As a major reference work, the encyclopedia has a very wide coverage of topics within the Quaternary sciences reflecting the complex and interdisciplinary nature of the science. Each of the major sections begins with a general overview of the topic prepared by a leading expert in the field. The major sections, for example, examine the analytical methods commonly used in paleoenvironmental reconstructions to unravel in a forensic-like manner the nature of former environments and the tempo of environmental change. Accordingly, a great range of topics such as the former extent of ice cover and nature of Quaternary glaciations, the biological responses and resultant fossil records to fluctuating climate, the expansion and contraction of desert environments, and global and local changes in relative sea levels are examined. Other topics covered include dating techniques, Quaternary stratigraphy, fluvial environments, lake level studies, paleosols, paleobotany, ancient DNA, paleolimnology, vertebrate studies, insect fossil studies, paleoceanography, stable isotope studies, ice core records, and human evolution in the Quaternary. One of the new sections in the encyclopedia examines the application of Quaternary proxy evidence in forensic science. All sections provide a clear summary of the latest advances in the fields of research.

This is an outstanding work and the editors and the publisher are to be congratulated for producing an encyclopedia that cogently summarizes the current state of the science.

A handwritten signature in black ink, appearing to read 'C. Murray-Wallace', with a stylized, flowing script.

INTRODUCTION

It has been my privilege to work with more than 420 leading Quaternary scientists in developing the second edition of the *Encyclopedia of Quaternary Science*. This team of writers and editors represents 28 countries in Europe, Asia, Africa, the Americas, Australia, and New Zealand. Starting with the first edition in 2006, I have had my finger on the pulse of Quaternary science, and this branch of science is truly pulsating! Information now comes from an incredible variety of disciplines: geochemistry, numerical modeling, history, vulcanology, paleobiology, nuclear physics, stratigraphy, sedimentology, climatology, anthropology, archaeology, glacial geology, soil science, ice-stream modeling – the list is staggering. This highly disparate group of people are bound together by one common thread: the desire to know the history of the planet during the last 2.6 million years – the time of the ice ages. For Quaternary scientists, this is a pressing need, not an idle curiosity. Any doubts about this statement can be easily dispelled by a consideration of the lengths to which many of them go to gather the necessary data. Some of them have worked for months in sub-zero temperatures on top of very high mountains, or near the center of polar ice sheets, collecting ice cores. Others have spent many weeks on some of the roughest seas in the world, drilling deep-sea sediment cores. Often the work is more mundane. An oxygen isotope curve for a lengthy marine sediment core represents thousands of hours of patiently picking tiny fossils from layer after layer of sediments, in order to obtain sufficient numbers of calcium carbonate shells to yield samples for isotopic analysis. A map showing proposed ice limits from the last glaciation represents thousands of hours of field mapping of glacial features by dozens of people. Why do all of these people devote their lives to this pursuit of knowledge? Does it really matter so much? The answer becomes clear when you step back and examine the topic of Quaternary science in its proper context.

The world we inhabit has largely been shaped by the events of the Quaternary. All the biological communities that exist today are the end product of a long series of species associations that came together in the past, largely driven by climatic change during the Pleistocene. We cannot properly understand the functioning of modern ecosystems without a solid knowledge of their history, any more than we can understand the plot of a long novel by reading just the final page. We are also living in a time of alarming climate changes. Even though the pace and intensity of some of these changes have not been seen in historical times, there were many rapid, large-scale climatic shifts in the Pleistocene. The best way to predict the effects of global warming on the planet's climate and ecosystems is to look at the history of similarly intense, rapid changes in the prehistoric past. The interval that is most relevant today is the most recent geologic period: the Quaternary. As human populations rise exponentially, increasing numbers of people are exposed to geologic hazards, such as earthquakes (and attendant tsunamis), and volcanic eruptions. These are short-lived events that take place only rarely in any one region. The interval between major events, such as volcanic eruptions, may be centuries or millennia. How do we come to grips with predicting the future likelihood of such erratic phenomena? Again, the answers come from piecing together the ancient history of such events, over many thousands of years.

The Quaternary has been the time when our own species came of age. The beginning of the Quaternary, roughly 2.6 million years ago, was about the time when the earliest member of our genus (*Homo*) first appeared in Africa. Pleistocene environments shaped the course of human evolution, culminating in anatomically modern *Homo sapiens* spreading from Africa throughout most of the world during the last glaciation. Even though human beings largely shape their own environments today, for the vast majority of our species' history, it has been the environment that has shaped us. Our direct ancestors' adaptations to environmental change are deeply ingrained in our genes. Thus, an understanding of the environmental conditions that shaped our species is critical to our understanding of humanity.

Quaternary science is a rapidly changing field, and the articles that appear in this encyclopedia reflect this. New dating techniques, such as cosmogenic nuclide dating, are revolutionizing our understanding of many earth surface processes. The ability to analyze increasingly smaller samples for radiocarbon and stable isotopes of oxygen and hydrogen means that we are gaining a level of precision in the reconstruction of past events that was unheard of just a few years ago. Stable isotope studies of air bubbles trapped in ice cores from Greenland and Antarctica have given Quaternary scientists an entirely new perspective on the rapidity and intensity of climatic change during the last glacial cycle and beyond. Likewise, the discovery of long sequences of annually laminated sediments in both marine and freshwater environments has provided a great leap forward in our ability to resolve the timing of environmental changes in nonpolar regions. The ability to extract and analyze ancient DNA sequences from Pleistocene fossils (both plants and animals) is revolutionizing the field of paleobiology. We are beginning to be able to trace the genetic lineages of a number of different organisms, from beetles to bison. In short, these are very exciting times to be a Quaternary scientist! While it is virtually impossible for any Quaternary researcher or student to keep abreast of all the new discoveries in this multifaceted science, this encyclopedia can be of great help. The articles contained here represent the state of the art in a huge variety of topics, and they offer the opportunity to dig deeper into their respective subjects by providing full citations of the most pertinent literature available. I invite you to come and explore the Quaternary Period in the pages that follow. It is a fascinating story.

HOW TO USE THE ENCYCLOPEDIA

The material in this encyclopedia is organized into two broad sections. At the start of Volume 1 are four *Introductory Articles* that serve as a broad introduction to the field. It is intended that these articles should serve as the first port of call for readers, to enable them to embark on any of the main entries without the need to consult other material beforehand.

Following the Introductory Articles, the main body of The Encyclopedia is arranged as a series of entries in alphabetical order. These entries fill the remainder of the volumes.

To help realize the full potential of the material in the Encyclopedia we have provided four features to help you find the topic of your choice: a contents list by subject; an alphabetical contents list; cross-references to other articles; and a full subject index.

1. Contents list by subject

Your first point of reference will probably be the contents list by subject. This list appears at the front of each volume, and groups the entries under subject headings describing the broad themes of Quaternary science. This will enable the reader to make quick connections between entries and to locate the entry of interest. Under each main section heading, you will find several subject areas and under each subject area is a list of those entries that covers aspects of that subject, together with the volume and page numbers on which these entries may be found.

2. Alphabetical contents list

The alphabetical contents list, which also appears at the front of each volume, lists the entries in the order in which they appear in the Encyclopedia. This list provides both the volume number and the page number of each entry.

You will find ‘dummy’ entries where obvious synonyms exist for entries or where we have grouped together related topics. Dummy entries appear in both the contents list and the body of the text.

Example

If you were attempting to locate material on *peat studies* via the alphabetical contents list:

PEAT STUDIES *see* PLANT MACROFOSSIL METHODS AND STUDIES: Mire and Peat Macros

The dummy entry directs you to the entry in which *peat* is covered.

If you were trying to locate the material by browsing through the text and you had looked up *Peat Studies*, then the following information would be provided in the dummy entry:

Peat Studies *see* PLANT MACROFOSSIL METHODS AND STUDIES: Mire and Peat Macros

3. Cross-references

All of the entries in the Encyclopedia have been extensively cross-referenced. The cross-references, which appear at the end of the entry, serve three different functions:

- i. To indicate if a topic is discussed in greater detail elsewhere.
- ii. To draw the reader’s attention to parallel discussions in other entries.
- iii. To indicate material that broadens the discussion.

Example

The following list of cross-references appear at the end of the entry GLACIAL LANDFORMS, ICE SHEETS | Growth and Decay

See also: **Introduction:** History of Quaternary Science; **Paleoclimate Reconstruction:** Sub-Milankovitch (DO/Heinrich) Events; **Glacial Climates:** Thermohaline Circulation; **Glaciation, Causes:** Astronomical Theory of Paleoclimates; **Paleoclimate Modeling:** Last Glacial Maximum GCMs; **Glaciations:** Overview; **Sea Level Studies:** Overview; Paleocceanography; **Ice Core Records:** Correlations Between Greenland and Antarctica.

Here you will find examples of all three functions of the cross-reference list: a topic discussed in greater detail elsewhere (e.g., **Paleoclimate Modeling:** Last Glacial Maximum GCMs), parallel discussion in other entries (e.g., **Glacial Climates:** Thermohaline Circulation), and reference to entries that broaden the discussion (e.g., **Glaciations:** Overview).

4. Index

The index provides you with the page number where the material is located. The index entries differentiate between material that is a whole entry, is part of an entry, or is data presented in a figure or a table. Detailed notes are provided on the opening page of the index.

5. Contributors

A full list of contributors is listed at the beginning of each volume.

CONTENTS LIST BY SUBJECT

Location references refer to the volume number and page number (separated by a colon)

Introduction and History of Science

INTRODUCTION | History of Quaternary Science, 1:1
INTRODUCTION | History of Dating Methods, 1:9
INTRODUCTION | Societal Relevance of Quaternary Research, 1:17

PALEOBOTANY | Overview of Terrestrial Pollen Data, 2:699

Pollen Studies

POLLEN ANALYSIS, PRINCIPLES, 3:794
POLLEN METHODS AND STUDIES | Use of Pollen as Climate Proxies, 3:805
POLLEN METHODS AND STUDIES | Surface Samples and Trapping, 3:839
POLLEN METHODS AND STUDIES | The Biome Approach to Reconstructing Past Vegetation, 3:861
POLLEN METHODS AND STUDIES | POLLSCAPE Model, 3:871
POLLEN METHODS AND STUDIES | Reconstructing Past Biodiversity Development, 3:816
POLLEN METHODS AND STUDIES | Numerical Analysis Methods, 3:821
POLLEN METHODS AND STUDIES | Changing Plant Distributions and Abundances, 3:854
POLLEN METHODS AND STUDIES | Stand-Scale Palynology, 3:846
PALEOBOTANY | Paleophytogeography, 2:730
POLLEN METHODS AND STUDIES | Databases and Their Application, 3:831

Charred Particle Analysis

PALEOBOTANY | Charred Particle Analyses, 2:716

Quaternary Pollen Records

POLLEN RECORDS, LAST INTERGLACIAL OF EUROPE, 4:1
POLLEN RECORDS, LATE PLEISTOCENE | Africa, 4:9
POLLEN RECORDS, LATE PLEISTOCENE | Australasia, 4:18
POLLEN RECORDS, LATE PLEISTOCENE | Northern Asia, 4:27

POLLEN RECORDS, LATE PLEISTOCENE | Northern North America, 4:39
 POLLEN RECORDS, LATE PLEISTOCENE | Western North America, 4:72
 POLLEN RECORDS, LATE PLEISTOCENE | South America, 4:52
 POLLEN RECORDS, LATE PLEISTOCENE | Middle and Late Pleistocene in Southern Europe, 4:63
 POLLEN RECORDS, POSTGLACIAL | Africa, 4:85
 POLLEN RECORDS, POSTGLACIAL | Australia and New Zealand, 4:104
 POLLEN RECORDS, POSTGLACIAL | Northeastern North America, 4:115
 POLLEN RECORDS, POSTGLACIAL | Northwestern North America, 4:124
 POLLEN RECORDS, POSTGLACIAL | Southeastern North America, 4:133
 POLLEN RECORDS, POSTGLACIAL | Southwestern North America, 4:142
 POLLEN RECORDS, POSTGLACIAL | South America, 4:156
 POLLEN RECORDS, POSTGLACIAL | Northern Asia, 4:164
 POLLEN RECORDS, POSTGLACIAL | Northern Europe, 4:173
 POLLEN RECORDS, POSTGLACIAL | Southern Europe, 4:179
 POLLEN METHODS AND STUDIES | Archaeological Applications, 3:880

Phytoliths

PHYTOLITHS, 3:582

Ancient Plant DNA

PALEOBOTANY | Ancient Plant DNA, 2:705

Plant Macrofossil Studies

PLANT MACROFOSSIL INTRODUCTION, 3:593
 PLANT MACROFOSSIL METHODS AND STUDIES | Surface Samples, Taphonomy, Representation, 3:684
 PLANT MACROFOSSIL METHODS AND STUDIES | Treeline Studies, 3:690
 PLANT MACROFOSSIL METHODS AND STUDIES | Megafossils, 3:621
 PLANT MACROFOSSIL METHODS AND STUDIES | Paleolimnological Applications, 3:657
 PLANT MACROFOSSIL METHODS AND STUDIES | CO₂ Reconstruction from Fossil Leaves, 3:613
 PLANT MACROFOSSIL METHODS AND STUDIES | Rodent Middens, 3:674

PLANT MACROFOSSIL METHODS AND STUDIES | Mire and Peat Macros, 3:637
 PLANT MACROFOSSIL METHODS AND STUDIES | Use in Environmental Archaeology, 3:699
 PLANT MACROFOSSIL METHODS AND STUDIES | Dendroarchaeology, 3:630
 PLANT MACROFOSSIL METHODS AND STUDIES | Validation of Pollen Studies, 3:725

Plant Macrofossil Records

PLANT MACROFOSSIL RECORDS | Arctic Eurasia, 3:733
 PLANT MACROFOSSIL RECORDS | Greenland, 3:760
 PLANT MACROFOSSIL RECORDS | Arctic North America, 3:746
 PLANT MACROFOSSIL RECORDS | Holocene North America, 3:768
 PLANT MACROFOSSIL RECORDS | Late Glacial Multidisciplinary Studies, 3:785

Diatom Studies

DIATOM INTRODUCTION, 1:471
 DIATOM METHODS | Data Interpretation, 1:489
 DIATOM RECORDS | North Atlantic and Arctic, 1:562
 DIATOM RECORDS | Pacific, 1:571
 DIATOM RECORDS | Antarctic Waters, 1:527
 DIATOM RECORDS | Diatom Fossil Records from Marine Laminated Sediments, 1:554
 DIATOM RECORDS | Freshwater Laminated Sequences, 1:540
 DIATOM RECORDS | Large Lakes, 1:546
 DIATOM METHODS | Salinity and Climate Reconstructions from Continental Lakes, 1:507
 DIATOM METHODS | $\delta^{18}\text{O}$ Records, 1:481
 PALEOBOTANY | Silicon Isotopes in Diatoms, 2:734
 DIATOM METHODS | Use in Archaeology, 1:516
 DIATOM METHODS | Diatomites: Their Formation, Distribution, and Uses, 1:501
 Structures and Applications of Biomarkers from Arctic Sea Ice Diatoms, 1:588

Paleolimnology

PALEOLIMNOLOGY | Overview of Paleolimnology, 3:259
 PALEOLIMNOLOGY | Lake Chemistry, 3:292
 PALEOLIMNOLOGY | Physical Properties of Lake Sediments, 3:300
 PALEOLIMNOLOGY | Cladocera, 3:271
 PALEOLIMNOLOGY | Freshwater Mollusks, 3:281

PALEOLIMNOLOGY | Contributions of
Paleolimnological Research to
Biogeography, 3:313
PALEOLIMNOLOGY | Pigment Studies, 3:326
PALEOLIMNOLOGY | Visible and Infrared
Spectroscopical Applications, 3:349
PALEOLIMNOLOGY | Multiproxy Approaches, 3:339

Vertebrate Studies

VERTEBRATE OVERVIEW, 4:590
VERTEBRATE RECORDS | Early Pleistocene, 4:599
VERTEBRATE RECORDS | Early and Middle
Pleistocene of Northern Eurasia, 4:605
VERTEBRATE RECORDS | Mid-Pleistocene of
Southern Asia, 4:651
VERTEBRATE RECORDS | Mid-Pleistocene of
Africa, 4:615
VERTEBRATE RECORDS | Mid-Pleistocene of
Australia, 4:621
VERTEBRATE RECORDS | Mid-Pleistocene of
Europe, 4:639
VERTEBRATE RECORDS | Mid-Pleistocene of
North America, 4:646
VERTEBRATE RECORDS | Late Pleistocene of
Africa, 4:664
VERTEBRATE RECORDS | Late Pleistocene of North
America, 4:673
VERTEBRATE RECORDS | Late Pleistocene of South
America, 4:680
VERTEBRATE RECORDS | Late Pleistocene of
Southeast Asia, 4:693
VERTEBRATE RECORDS | Late Pleistocene
Megafaunal Extinctions, 4:700
VERTEBRATE RECORDS | Late Pleistocene
Mummified Mammals, 4:713
VERTEBRATE STUDIES | Ancient DNA, 4:719
VERTEBRATE STUDIES | Speciation and
Evolutionary Trends in Quaternary
Vertebrates, 4:723
VERTEBRATE STUDIES | Dwarfing and Gigantism in
Quaternary Vertebrates, 4:733
VERTEBRATE STUDIES | Interactions with
Hominids, 4:748

Insect Fossil Studies

Beetle Studies

BEETLE RECORDS | Overview, 1:161
BEETLE RECORDS | Late Tertiary and Early
Quaternary Records, 1:173
BEETLE RECORDS | Middle Pleistocene of Western
Europe, 1:184

BEETLE RECORDS | Late Pleistocene of
Europe, 1:200
BEETLE RECORDS | Late Pleistocene of North
America, 1:221
BEETLE RECORDS | Late Pleistocene of South
America, 1:235
BEETLE RECORDS | Late Pleistocene of
Australia, 1:191
BEETLE RECORDS | Late Pleistocene of Northern
Asia, 1:255
BEETLE RECORDS | Late Pleistocene of Japan, 1:207
BEETLE RECORDS | Late Pleistocene of New
Zealand, 1:244
BEETLE RECORDS | Postglacial Europe, 1:274
BEETLE RECORDS | Postglacial North America, 1:282

Chironomid Studies

CHIRONOMID RECORDS | Chironomid
Overview, 1:355
CHIRONOMID RECORDS | Late Pleistocene of
Europe, 1:373
CHIRONOMID RECORDS | Africa, 1:361
CHIRONOMID RECORDS | Late Pleistocene of
Europe, 1:373
CHIRONOMID RECORDS | Postglacial
Europe, 1:386
CHIRONOMID RECORDS | Postglacial Southern
Hemisphere, 1:398

Oribatid Mite Studies

ORIBATID MITES, 2:680

Paleoceanography

Paleoceanographic Studies

PALEOCEANOGRAPHY | Paleoceanography An
Overview, 2:745
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Corals, Sclerosponges and Mollusks, 2:795
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Benthic Foraminifera, 2:765
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Planktic Foraminifera, 2:825
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Radiolarians and Silicoflagellates, 2:830
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Coccolithophores, 2:783
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Alkenone Paleothermometry Based on the
Haptophyte Algae, 2:755
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Marine Diatoms, 2:816

PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Dinoflagellates, 2:800

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Terrigenous
Sediments, 2:941

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Oxygen Isotopic
Composition of Seawater, 2:915

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Oxygen-Isotope
Stratigraphy of the Oceans, 2:907

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Dissolution of Deep-Sea
Carbonates, 2:859

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Mg/Ca and Sr/Ca
Paleothermometry from Calcareous Marine
Fossils, 2:871

PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Temperature Proxies Census Counts, 2:841

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Salinity Proxies
 $\delta^{18}\text{O}$, 2:932

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Nutrient Proxies, 2:899

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Carbon Cycle
Proxies, 2:849

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Radioisotope
Proxies, 2:923

PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Biomarkers Indicators of Past Climate, 2:775

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Magnetic Proxies and
Susceptibility, 2:884

Paleoceanographic Records

PALEOCEANOGRAPHY, RECORDS | Early
Pleistocene, 3:1

PALEOCEANOGRAPHY, RECORDS | Late
Pleistocene North Atlantic, 3:9

PALEOCEANOGRAPHY, RECORDS | Late
Pleistocene South Atlantic, 3:18

PALEOCEANOGRAPHY, RECORDS | Late
Pleistocene North Pacific, 3:33

PALEOCEANOGRAPHY, RECORDS | Postglacial
North Atlantic, 3:55

PALEOCEANOGRAPHY, RECORDS | Postglacial
North Pacific, 3:62

PALEOCEANOGRAPHY, RECORDS | Postglacial
South Pacific, 3:73

PALEOCEANOGRAPHY, RECORDS | Postglacial
Indian Ocean, 3:46

Ice Core Studies

Ice Core Studies

ICE CORE METHODS | Overview, 2:278

ICE CORES | History of Research, Greenland and
Antarctica, 2:435

ICE CORE METHODS | Chronologies, 2:303

ICE CORE METHODS | Stable Isotopes, 2:347

ICE CORE METHODS | Conductivity Studies, 2:319

ICE CORE METHODS | Glaciochemistry, 2:326

ICE CORE METHODS | Biological Material, 2:288

ICE CORE METHODS | Microparticle and Trace
Element Studies, 2:342

Introduction

The Last Interglacial represents the most recent geological interval during which conditions were similar to the present interglacial, but with negligible anthropogenic effects. The most widely used stratigraphic unit of the Last Interglacial is marine isotope stage (MIS) 5e of the deep-sea stratigraphy (Shackleton, 1969), reflecting an interval of minimum global ice volume with sea level as high, or indeed higher, than present. The oldest assignment of a terrestrial deposit to the Last Interglacial is the Eemian, the term introduced by Harting (1874) to describe a subsoil characterized by warm marine mollusks in the Eem valley near Amersfoort in The Netherlands. Deposits of similar age were also found in Germany and Denmark, and a pollen zonation scheme was described by Jessen and Milthers (1928). The Amersfoort site has been used as the type locality for the Eemian Stage (Zagwijn, 1961) for northwest Europe, but because the sequence was condensed, a more complete sedimentary record at Amsterdam terminal has been chosen as the lectostratotype (Cleveringa et al., 2000). The succession of pollen zones described in The Netherlands can be observed in numerous deposits across northwest Europe, with some vegetation events considered sufficiently time-parallel (Zagwijn, 1996). This has led to the use of the term 'Eemian' being applied across northwest Europe, often extended well beyond this region over the whole of Europe, and also used interchangeably with 'Last Interglacial' in more general contexts (e.g., the 'Eemian' in Greenland ice cores). Kukla et al. (2002) have pointed out that although the term Eemian has been used as a chronostratigraphic stage (i.e., with time-parallel boundaries everywhere), in local contexts it is defined using biostratigraphic or climatostratigraphic units whose boundaries may be diachronous; they have therefore recommended that the use of the term 'Eemian' be restricted to northwest Europe. Thus, the generic term 'Last Interglacial' is here used to describe the forest interval in different parts of Europe, which is broadly equivalent with MIS 5e, although their upper and lower boundaries may diverge in detail, depending on location.

Depositional Environments and Vegetation Development

Given its stratigraphical position, the Last Interglacial has been the most extensively studied pre-Holocene stage. South of the last (Weichselian) glacial limit, hundreds of former lake basins overlie sediments of the penultimate (late Saalian: MIS 6) glaciation. These represent kettle hole features formed by buried ice during the retreat of the Saalian ice and filled by Last Interglacial organic sediments, overlain by minerogenic sediments of the ensuing cold interval. In coastal lowlands, Last

Interglacial marine sediments are often interlayered with lacustrine beds, as in the Eemian stratotype at Amersfoort. North of the Weichselian ice limit, several Last Interglacial deposits have also been identified, covered by Weichselian till or deformed by ice (Mangerud, 1991). A prominent feature is the existence of several terrestrial sites with Last Interglacial marine sediments, indicating an extensive marine transgression. The so-called 'Eemian Sea' (Figure 1) flooded main river valleys along the North Sea coast and linked the Baltic Sea and Arctic Ocean over Lake Ladoga, Lake Onega, and the White Sea, turning Fennoscandia into an island (see review by Donner (1995)). This resulted from a combination of greater crustal downwarping and a more easterly located center of the late Saalian ice sheet relative to the Weichselian, rapid deglaciation and somewhat higher Last Interglacial sea levels. South of the late Saalian glacial limit, a concentration of deposits is found in the Alpine foreland, formed in depressions left by the penultimate Alpine glaciation. Additional deposits have been found in similar geomorphological settings related to local ice caps, such as the Grande Pile basin in the Vosges mountains (Woillard, 1978). These often contain longer polleniferous sequences than sites further north, with the entire last climatic cycle represented at Grande Pile. In southern Europe, the overall density of pollen sites of Last Interglacial age is low. However, they usually form part of long sequences that have accumulated relatively undisturbed in volcanic crater lakes or tectonic basins, providing complete records with clear chronostratigraphical relations.

Analyses of these deposits have produced a substantial body of palynological evidence, providing an insight into the vegetational character of large parts of Europe (see Figure 2 for location of some of the sites discussed). Within the classic Eemian area of western and central Europe, pollen diagrams show a characteristic succession of overlapping peaks, suggesting a uniform vegetation development across large regions (e.g., Grüger (1991) and Zagwijn (1996)). Despite varying nomenclatures, pollen zonation schemes from this area are therefore easily correlated (Table 1) and reveal the following broad patterns: *Betula* (birch) formed the first forests followed closely by *Pinus* (pine). These were replaced by *Ulmus* (elm) and *Quercus* (oak) and then by *Corylus* (hazel). Compared to the Holocene, hazel appears to have spread more slowly during the Last Interglacial (i.e., its peak is recorded after, rather than before or during, the oak peak). A *Corylus*–*Taxus*–*Tilia* phase followed, noted by the relatively high values of *Taxus* (yew) achieved in certain places and by the presence of *Tilia tomentosa* (linden), today confined to the Balkans and the Near East (Grüger, 1991). A characteristic feature of the Last Interglacial is the ensuing expansion of *Carpinus* (hornbeam), which completely dominated large parts of European deciduous forests. Following that, *Abies* (fir) and/or *Picea* (spruce) populations expanded. The closing stages of the interglacial were

marked by the re-expansion of pine and birch. Perhaps equally characteristic of the Eemian as the hornbeam phase is the absence of *Fagus* (beech) across Europe, except in Italy where low but continuous presence has been recorded (Follieri et al., 1988; Allen et al., 2005). It remains unclear whether climatic

Figure 1 Reconstruction of European paleoenvironments during the Last Interglacial optimum ~125 ka. Vegetation units: boreal forest (bof), mixed coniferous-deciduous forest (cdf), temperate deciduous forest (def), Mediterranean evergreen forest/scrub (med). From van Andel TH and Tzedakis PC (1995) Paleolithic landscapes in Europe and environs, 150 000–25 000 years ago: An overview. *Quaternary Science Reviews* 15: 481–500.

conditions, competition, pathogenic attack, or a combination of these factors during the Last Interglacial (or perhaps during the preceding cold stage) inhibited the expansion of beech. Despite the overall similarities, Zagwijn (1996) has also drawn attention to some regional peculiarities. For example, the yew peak is not strongly expressed in eastern Poland, while the linden peak is not apparent in the southernmost and westernmost sites of the classic Eemian area. The linden peak is most strongly expressed in the north German lowland and can be traced eastward into Poland, Belarus, and western Russia, where yew is absent, thus forming a valuable east-west correlation tool.

Beyond the classic Eemian area, Last Interglacial vegetation successions become, unsurprisingly, modified. Mangerud (1991) considered a transect of sites from northern Germany, mid-Jutland, and western Norway and pointed out that linden and fir dropped out of the succession in Denmark, while in western Norway two additional taxa (yew and hornbeam) were removed. This produces a floristically rather impoverished interglacial succession at Fjøsanger, near Bergen, characterized by pine and birch, an early immigration of oak and some elm, followed by the expansion of hazel and then spruce. Further east, oak and particularly hazel are more strongly represented in diagrams from Ostrobothnia than in the Holocene, while linden is absent. Hornbeam is represented in records from southern Sweden and is also encountered in diagrams from Finland as far north as Ostrobothnia, where it is usually absent in the Holocene. Further north, in Swedish and Finnish Lapland diagrams are dominated by birch or pine with traces of hazel followed by a peak in spruce (see review by Donner (1995)).

In southern Europe, examination of the available data reveals specific regional patterns in the character of the interglacial succession. Thus, during the Last Interglacial, Greek (Tzedakis et al., 2003) and Italian sites (Follieri et al., 1988; Allen et al., 2005) show deciduous oak and elm expanding first, followed by an increase in Mediterranean sclerophylls,

Question marks refer to durations extrapolated on the basis of sediment accumulation rates.

dominated by the largest preanthropogenic peak in *Olea* (olive) in the last 430 ka. About 3 ka into the interglacial, hornbeam and *Ostrya* (hophornbeam) populations expanded; fir then increased and remained dominant until the end of the interglacial at Lago Grande di Monticchio (Allen et al., 2005), while at Ioannina, the final phase of the interglacial shows a re-expansion of deciduous oak (Tzedakis et al., 2003). In contrast to the floristically diverse interglacial successions at wetter sites, records from southernmost Europe and from generally drier locations show a vegetational development that is mostly dominated by deciduous and evergreen oak, other mediterranean sclerophylls, and pine and *Juniperus* (juniper) (e.g., Sánchez Goñi et al. (2005)). In the Massif Central, high-altitude sites (Figure 3) show both central European and Mediterranean affinities (e.g., de Beaulieu and Reille, 1992), thus conveniently linking the stratigraphies north and south of the Alps. Of particular interest are traces of Mediterranean taxa (olive, *Pistacia* (pistachio)) during the hazel zone, a reflection of their large population expansion at lower altitudes.

Duration and Timing of Events

The first important contribution toward an understanding of the duration of the Last Interglacial on land was made by Shackleton (1969) who proposed that the Eemian was not equivalent to the entire MIS 5 of the deep-sea stratigraphy, but rather to an interval within it (MIS 5e). This meant that the Last Interglacial did not have a duration of half an eccentricity cycle (~50 ka), but rather half a precessional cycle

(~10 ka). Astronomical calibration of the marine timescale provided an age of 128 ka for the mid-point of the glacial-to-interglacial transition and 116 ka for the interglacial-to-stadial transition. This appeared to agree with the first Eemian floating chronology from Bispingen, Germany, which indicated a duration of ~11 ka (Müller, 1974). This figure was based on counts of annual laminations spanning part of the Eemian and extrapolation based on sedimentation rates for the remainder. Although the emergent chronology was not anchored by any absolute dates, the good correspondence between the marine and terrestrial estimates for the duration of the Last Interglacial led to the assumption that the lower and upper boundaries of the MIS 5e and the Eemian must have been broadly synchronous.

This view was challenged by Kukla et al. (1997) who tuned the Grande Pile pollen sequence (Woillard, 1978) to the marine stratigraphy of North Atlantic record V29-191 (McManus et al., 1994). This indicated that the terrestrial interglacial lasted 23 ka (130–107 ka) and extended well into MIS 5d until the onset of significant ice rafting in the North Atlantic (event C24 of McManus et al. (1994)). To avoid any circularity arising from aligning terrestrial records to the marine stratigraphy, Shackleton et al. (2002) combined high-resolution foraminiferal isotopic and pollen analyses in a deep-sea core (MD95-2042) off southwest Portugal. The chronology of the sequence was based on inferred sea-level stillstands correlated with radiometrically dated marine coral terraces. This meant that pollen-stratigraphical changes could be directly compared with changes in global ice volume and could also be placed within an absolute chronological framework (Figure 4). The length of the forested interval was 16 ka, with the onset at

Ribains maar (1075 a.s.l.)

Figure 3 Last Interglacial pollen diagram of selected taxa from Ribains maar, Massif Central (de Beaulieu and Reille, 1992), displaying northern and southern European characteristics. Dots indicate pollen values below 2.5%.

126 ka and the end at 110 ka, while the lower and upper age boundaries for MIS 5e were 132 ka and 115 ka, respectively. Although the actual date for the MIS 6/5e boundary (the mid-point of the deglaciation) may be a matter of some debate, the phase relationship between pollen and benthic $\delta^{18}\text{O}$ records derived from the same sediment sequence is independent of the precise chronology and clearly reveals that neither the lower nor upper boundaries of terrestrial and marine stages are coincident. The onset of interglacial conditions on land (expressed by the full expansion of tree populations) occurred within MIS 5e, well after deglaciation was complete, and it was coincident with a rise to peak sea-surface temperatures (SSTs). This conflicts with the Dutch scheme, where sea level continued to rise during the first 3–4 ka (into the hazel zone) of the terrestrial interglacial (e.g., Zagwijn (1983)). However, the Scandinavian ice sheet reached The Netherlands during MIS 6 and therefore local sea-level history is complicated by glacio-isostatic movements (e.g., Lambeck and Chappell (2001)). At the end of MIS 5e (115 ka), SSTs began a gradual decline, but interglacial conditions persisted on land with tree populations surviving into MIS 5d, albeit at reduced densities. The onset of significant ice rafting in the North Atlantic after 110 ka led to the disruption of the thermohaline circulation and an abrupt change in temperature and precipitation regimes, leading to the elimination of tree populations in southwest Iberia.

On this basis, the timing of events in Europe can be broadly summarized as follows. Southern European sites show evidence of a step-like transition to full interglacial conditions, with an early small increase mainly in oak populations around 129 ka, before a second large expansion of tree populations, defining the onset of the interglacial at ca. 127–126 ka (Figure 5). This is preceded by a Late Glacial vegetation oscillation, coincident with Heinrich Event 11 (HE 11) (Shackleton et al., 2002). However, the magnitude of this oscillation appears to have been smaller than the Younger Dryas during the most recent deglaciation. This means that there was no significant setback to the northward spread of tree populations and can partly explain the rapid vegetation succession that characterizes the early Eemian (as determined in annually laminated sediments). Thus, the degree of diachroneity between southern and northern Europe in the early part of the Last Interglacial appears to have been small (on the order of a few hundred years). However, Müller and Kukla (2004) proposed that north of 50° N, pine and birch continued to dominate landscapes for the first 3–4 ka of the interglacial, and only after the Nordic Seas had warmed sufficiently by 124–123 ka, thermophilous taxa did expand in these areas. The problem with this scheme is that during the early Holocene, radiocarbon dates show that the pine/birch phase did not last more than 1 ka and, if anything, the succession of different zones in the early Eemian is thought to have been even faster. The most parsimonious

Figure 4 (a) Benthic and planktonic $\delta^{18}O$ data and summary pollen curves from MD95-2042, off southwest Portugal (Shackleton et al., 2002); (b) arboreal pollen (AP) percentages from Bispingen, Germany (Müller, 1974); the onset of the Eemian is here aligned with the terrestrial interglacial in MD95-2042; and (c) June insolation 65° N. (Data from Berger (1978)).

interpretation would be that at ~125 ka southern Europe was characterized by a significant expansion of Mediterranean vegetation (with a high proportion of olive), a reflection of hot summers associated with the insolation maximum, while north of the Alps deciduous forest (mainly hazel) dominated (Figure 1). The hornbeam expansion occurred around 123 ka in the south (Tzedakis et al., 2003; Sánchez-Góñi et al., 2005; Allen et al. 2005) with some degree of S–N diachroneity as shown in the timing of its appearance between Ribains and Grande Pile (de Beaulieu and Reille, 1992). After 120 ka, a reduction in boreal summer insolation led to a decrease in temperatures and an expansion of spruce/fir in northern Europe, followed by taiga after 118 ka. An episode involving a brief reduction in forest cover during the second part of the interglacial ~118 ka is recorded in some southern European sequences (e.g., de Beaulieu and Reille (1992), Shackleton et al. (2002), Tzedakis et al. (2003)). This may be coeval with changes in North Atlantic circulation, but lack of detailed chronological control makes correlations difficult. Studies from annually laminated sites from northern Germany suggest that the elimination of tree populations occurred around

115 ka, near the MIS 5e/5d transition (e.g., Müller (1974)). However, independent chronologies from Portugal (Shackleton et al., 2002), Italy (Allen et al., 2005), and Greece (Tzedakis et al., 2003) suggest that southern European tree populations persisted well into the interval of ice growth until ca. 110–111 ka. Tzedakis (2003) has suggested that this N–S diachroneity may be a reflection of the effects of different bioclimatic parameters, limiting tree growth in the two areas. In the North, tree-population decline is associated with a decrease in the amount of accumulated growing-season warmth as a result of orbital changes after 120 ka. Model simulations suggest that after 120 ka, sea ice and tundra vegetation expanded between 60–90° N (Crucifix and Loutre, 2002) and thus by 115 ka the tundra/taiga boundary may have migrated to ~50° N. Although the orbital changes occurred gradually, the abrupt decline in tree populations at 115 ka suggests a threshold response. Cooling of the Nordic seas may have also contributed to the elimination of forest in northern Germany and Scandinavia by 115 ka (Müller and Kukla, 2004). In southern Europe, however, forest is not limited by the degree of summer warmth, but largely by moisture availability. During the early stages of ice growth (115–110 ka), oceanic heat transport continued to operate over most of the subpolar North Atlantic (e.g., Chapman and Shackleton, 1999), providing a moisture source for tree populations in southern Europe. However, once sufficient ice volume had accumulated to initiate ice rafting in the North Atlantic and disruption of the thermohaline circulation, it led to a reduction in moisture availability and the demise of southern European tree populations. During the closing stages of the interglacial, southern European pollen records show a brief open vegetation event, followed by a re-expansion of tree populations before a larger increase in open vegetation cover indicates the onset of stadial conditions, associated with the occurrence of ice-rafting event C24 (Figure 5).

Some uncertainty still surrounds the length of the forest interval in the 40–50° N band. Did the interglacial there end at ~115 ka, ~110 ka, or somewhere in between? The answer may lie in the stratigraphical thickness of the stadial interval following the end of the Eemian. The Melisey I stadial appears to be stratigraphically very short and is immediately followed by a forest expansion associated with the St. Germain Ia interstadial. Although decreases in sediment accumulation rates may have contributed to that, the same pattern of stratigraphical length replicated across different depositional environments suggests real differences in time span. An argument may, therefore, be made that the end of the Last Interglacial in this region could not have happened at 115 ka, because that would imply that the St. Germain Ia interstadial tree expansion would have occurred before 110 ka, which creates an impossible asymmetry with southern European sequences. Decreases in growing-season warmth and/or cooling of Nordic seas would have a limited impact at this latitude, and therefore taiga could persist until 110 ka. If correct, this would imply a steep vegetation gradient centered around 50° N during the first-half of MIS 5d.

While this view of the timing of changes represents an advance over earlier schemes, some questions remain: (1) Does the onset of the Last Interglacial show a lagged tree population response relative to deglaciation everywhere, or is it geographically dependent? It is interesting to note, for example, that in a combined foraminiferal isotope and pollen study in a deep-sea

Figure 5 (a) $\delta^{18}\text{O}$ composition of ice in the NGRIP record (North Greenland Ice Core Members (2004). High-resolution record of Northern Hemisphere climate extending into the last interglacial period. *Nature* 431, 147-151). (b) Planktonic $\delta^{18}\text{O}$ data from MD95-2042, off southwest Portugal (Shackleton et al., 2002). (c) $\delta^{18}\text{O}$ composition of benthic Foraminifera (solid line); and (d) relative abundance of ice-rafted detritus (IRD) grains in $>150\ \mu\text{m}$ sediment fraction (dashed line) in core NEAP 18 K in the North Atlantic (Chapman and Shackleton, 1999). Age model used here is based on alignment to the $\delta^{18}\text{O}_{\text{benthic}}$ record of MD95-2042 (Shackleton et al., 2002). (e) Temperate tree pollen percentage from Ioannina I-284; age model is based on a pollen-orbital tuning procedure (Tzedakis et al., 2003). Position of marine isotope and terrestrial stage boundaries shown. 'MI,' 'SG Ia,' 'Mo,' and 'SG Ic' refer to Melisay I, St. Germain Ia, Montaigu, and St. Germain Ic intervals, respectively, as recognized in the Grande Pile pollen record (Woillard, 1978).

core of southeastern USA, the marine and terrestrial stage boundaries coincide at the onset of the Last Interglacial (Heusser and Oppo, 2003). (2) If deglaciation had reached mid-point at $\sim 132\ \text{ka}$ (or earlier) and was complete by ca. 128–127 ka, what could have caused the postulated ice-rafting event (HE 11) at $\sim 128\ \text{ka}$? New evidence from the South China Sea suggests that the demise of ice sheets did not precede boreal summer insolation increase and that the timing of deglaciation is in agreement with Milankovitch theory (Oppo and Sun, 2005). This means that the MIS 6/5e boundary should be placed somewhere around 129 ka. If correct, then the MD95-2042 chronology of Shackleton et al. (2002) may be in need of revision. However, this would shift the onset of the terrestrial interglacial and timing of vegetation events by 3 ka toward younger ages, because the phase lag between the marine and terrestrial boundary is fixed in the same sequence and estimated as $\sim 5\ \text{ka}$. This would imply that the expansion of mediterranean taxa and the olive event took place ca. 124–123 ka, much later than the summer insolation maximum at 127 ka that is thought to have caused it. However, Skinner and Shackleton (2005) showed that changes

in deep-water hydrography in the Portuguese margin during Termination I may lead to apparent differences in the timing of changes in the benthic isotope curve of up to 3–4 ka compared to the equatorial Pacific. By extension, the phase lag of 5 ka for Termination II between marine and terrestrial stages may be overestimated, with most of the early decrease in $\delta^{18}\text{O}_{\text{benthic}}$ values in MD95-2042 attributed to a rise in deep-water temperature and water-mass changes, while the glacio-eustatic sea-level change occurred later. This would reconcile any conflicting dates, producing the following possible timing of events: onset of MIS 5e at $\sim 129\ \text{ka}$, HE 11 at $\sim 128\ \text{ka}$, SST increase and onset of terrestrial interglacial at $\sim 127\ \text{ka}$, expansion of mediterranean taxa at $\sim 126\ \text{ka}$.

Vegetation Character and Comparisons with the Holocene

A striking pattern of the Last Interglacial is the uniform vegetation development across large regions of western and central

Figure 6 Timing of Holocene and Last Interglacial sea-level highstands and climatic optima in northern and southern Europe relative to the June 65° N insolation curve. From Berger A (1978).

Europe. This similarity becomes even more intriguing when compared to the large degree of variability of the Holocene vegetation succession across the same geographical areas, which in turn raises questions regarding the effects of small-scale anthropogenic disturbance on early Holocene landscapes. In addition, the different distribution of land and sea may have played a role in determining the vegetation character. The presence of the Eemian Sea must have led to milder and more equable climate conditions in the surrounding landmasses. This would have contributed to the establishment of temperate forests and might perhaps go some way in explaining the uniformity of Eemian vegetation over such a large area.

Considering the overall vegetational character of the Last Interglacial across Europe, what emerges is that the climate at the peak of the interglacial was warmer than at any time during the Holocene. This is based on the presence of pollen and macroremains of thermophilous terrestrial and water plants north of their Holocene ranges (e.g., Phillips (1974), Donner (1995)). The question, of course, is when exactly was the interglacial optimum? It has often been assumed that this occurred in the hornbeam zone, mainly on the basis of Holocene analogies. The millennium around 6¹⁴C ka BP (~6.85 cal ka BP) has often been considered as the time of maximum summer warmth in mid- to high latitudes of the Northern Hemisphere (although this applies mainly to Scandinavia, Britain, and the Alps, where it was first defined, and not to southern Europe, where it occurred ~9¹⁴C ka BP (~10 ka)). If the Holocene peak for northern Europe were considered to lie somewhere around 6.85 ka (i.e., ~4.65 ka into the interglacial), then by analogy the same point would lie somewhere in the hornbeam zone of the Last Interglacial. The problem is that the assumption of symmetry in the timing of events between the two interglacials may not be tenable (Figure 6). Sea-level reconstructions based on coral dates (Lambeck and Chappell, 2001) suggest that the Holocene highstand was reached ~7 ka (i.e., 4 ka after the boreal summer insolation peak at 11 ka), while that of the Last Interglacial was reached by ~127 ka

(coeval with the insolation peak). Thus, whereas during the Holocene the presence of ice still continued to influence high-latitude climate and vegetation well into the interglacial, the same did not occur during the Last Interglacial. This means that the optimum of the Last Interglacial occurred earlier (~125 ka) compared to that of the Holocene, closely following the timing of the insolation peak. This would coincide with the olive event in southern Europe and the hazel phase north of the Alps, rather than the hornbeam phase. What emerges is that the timing of the interglacial optimum in southern Europe appears to be more closely associated with the insolation peak and less influenced by the timing of deglaciation. On the other hand, the timing of the optimum in northern Europe varies between interglacials depending on the amount of residual ice volume.

Introduction

Africa is a unique continent with a complex and, indeed, fascinating array of contemporary physical environments associated with prolific biological diversity. Its fauna and flora have been shaped by the combined forces of evolutionary, geological, and climatic change along a trajectory that has become modified, especially so in the relatively recent past, by human activities. Quaternary environmental changes in Africa have been complex, frequent, and of high amplitude, although this is a view of environmental dynamics on the continent that has emerged only in the last few decades. It is important, then, that as accurate a picture of these changes as possible be developed so that we may more fully understand the contemporary status of African biogeography and be able to explore appropriate scenarios of future climate change and its implications. Pollen records, so valuable in reconstructing terrestrial environmental conditions in the Quaternary, have facilitated the compilation of a late Pleistocene vegetation history for Africa, although the temporal and spatial resolution is vastly inferior to that of temperate Europe or North America. As of 2011, the European Pollen Data Base, for example, has more than 1000 pollen records for the late Quaternary, representative of a geographical area of approximately 10 million km². The African Pollen Database (<http://medias.obs-mip.fr/apd/>), on the other hand, has somewhat less than 270 records even though it is the second largest continent on earth and spans an area more than 30 million km².

African pollen records for the late Pleistocene are restricted in number due to a combination of the relatively few studies that have been attempted and environmental conditions that are not always conducive to pollen preservation. This is especially the case in arid and semiarid environments where

organic sediments, traditionally the main source of subfossil pollen, are relatively unusual. Nevertheless, the picture that has emerged of African vegetation at, for example, the Last Glacial Maximum (LGM, ca. 26.5–19 ka; cf. [Clark et al., 2009](#)), is becoming clearer, based on pollen accumulations across a range of different sedimentary environments, including upland bogs and mires, lowland wetlands, lakes, pans, caves, middens, and coastal and marine sediments ([Elena et al., 2000](#)). However, the temporal and spatial coverage of the record remains very incomplete, and there are very large areas of the continent for which remarkably little is known about the development of late Quaternary vegetation patterns. As a result, it becomes necessary, as is the case with the biomization procedure followed by [Elena et al. \(2000\)](#) to interpolate the late Pleistocene paleoecology of much of Africa from the relatively few reliable records that do exist. One significant methodological advance that has emerged recently has been the quantification of the relationships between pollen, plants, and climate at the continental scale employing the African Pollen Database (e.g., [Watrin et al., 2007](#)). The modeling of plant distribution data, pollen percentages, and a climate response surface is used to identify plant taxa that illustrate a high degree of correspondence with climate at the regional scale and, in so doing, take a step toward more reliable vegetation and climate reconstructions for the late Quaternary.

Spanning latitudes 30 degrees north and south of the equator, the continent of Africa classically illustrates how the interactions between underlying geology, soils and geomorphology, and climate have combined over time to produce the contemporary distribution of its major biomes. Broadly speaking, these are identified as several major biomes ([Figure 1](#)), namely, tropical rainforest, savanna woodlands and grasslands, arid and semiarid formations, shrublands under a Mediterranean-type

Figure 1 The present potential vegetation of Africa. Adapted from Adams JM and Faure H (1997) (eds.) *Review and Atlas of Palaeovegetation: Preliminary Land Ecosystem Maps of the World since the Last Glacial Maximum*. climate, and upland or montane regions (Meadows, 1996). This general biogeographical framework is used here as a basis for the description and explanation of late Pleistocene pollen records of Africa. Rather than attempting to describe the entire late Pleistocene, the focus is on the LGM, taken to be coincident with the time when global ice volumes were at their maximum values and sea levels at minima, that is, between 26.5 and 19 ka (Clark et al., 2009), and representative of a time during which global temperatures were significantly lower than today. A summary of the LGM vegetation distribution is shown in Figure 2, revised and adapted from Adams and Faure (1997).

Tropical Rainforests

Given the importance of tropical rainforests in the context of biodiversity and the function of major global biogeochemical cycles, it is frustrating that there are so few pollen records for the late Pleistocene in Africa. Indeed, the first published pollen records for the equatorial forests of Africa were produced little more than two decades ago for two lakes in West Africa (Maley, 1991). There remain rather few terrestrial sites for which there are vegetation histories spanning the LGM from tropical

lowland forests of Africa, although the Holocene is better represented (see Lezine, this volume). Nevertheless, the pollen sequence from Lake Barombi Mbo, Cameroon, has now been more precisely interpreted (Lebamba et al., 2010) and provides an opportunity to glimpse this crucial period of vegetation change from the perspective of the largest area of tropical rainforest outside the Amazon basin.

The mechanisms underlying tropical forest diversity are not definitively known, but the original idea that long-term environmental stability was a principal factor has long since been laid to rest (Meadows, 1999). The replacement of this idea came with the realization, spawned by paleoecological studies, that the tropics – far from being immutable and static over extended periods of geological time – had been subject to major climatic fluctuations during the Quaternary. An alternative viewpoint arose that interpreted areas (habitat islands) of elevated diversity and levels of endemism within the tropics as the Pleistocene refugia of rainforest taxa (Connor, 1986). According to this view, these areas represented places of refuge at moderate altitude, where plant and animal species adapted to the hot and humid climates of lowland equatorial regions survived during the emerging cooler and drier climates of the glacials, when the savannas became much more widespread.

Figure 2 LGM vegetation of Africa. Localities mentioned in the text: (1) Tigalmamine, (2) Lake Ifrah, (3) Tibesti, (4) Lake Bosumtwi, (5) Dahomey Gap, (6) Lake Barombi Mbo, (7) Ngamakala, (8) Congo River fan, (9) ODP 1078C, (10) GeoB 1023–5, (11) Brandberg, (12) GeoB 1711–4, (13) Sossusvlei, (14) Pakhuis (15) Elands Bay, (16) Rietvlei, (17) Tswaing Crater, (18) Mfabeni Peatland, (19) Lake Tritrivakely, (20) Lake Malawi, (21) Lake Masoko, (22) Lake Rukwa, (23) Lake Tanganyika, (24) Dama Swamp, Iringa, (25) Deva-Deva, and (26) Lake Tana. Adapted from Adams JM and Faure H (1997) (eds.) *Review and Atlas of Palaeovegetation: Preliminary Land Ecosystem Maps of the World since the Last Glacial Maximum*. Oakridge, TN: Oak Ridge National Laboratory (<http://www.esd.ornl.gov/projects/gen/adams1.html>).

This view was not without its critics (Connor, 1986), and interpretation of paleoecological evidence from the equatorial region, most especially pollen analysis, led to a reassessment of the elegantly simple refugium hypothesis. The situation is far more complex than earlier viewpoints would have suggested and, certainly for South America, a simplistic view of the refugium hypothesis cannot be upheld (Bush, 2005).

A comprehensive biogeographical understanding of the Quaternary history of tropical lowland forests of Africa has proved elusive. Cooler temperatures, on the order of 4–5 °C lower than present, are uniformly indicated in the pollen records for the LGM. There appears to be considerable expansion of grassland and tropical seasonal forest at the expense of tropical rainforest in the cold phases, indicative of drier conditions. The so-called Dahomey Gap in West Africa was at its most extensive during these times (Dupont and Weinelt, 1996), although rainforest does appear to have survived in certain localities (Dupont et al., 2000; Jahns et al., 1998). Receiving annual rainfall today in excess of 2300 mm, the savannas in the vicinity of Lake Barombi Mbo are themselves

regarded as relict, left over from a time (the LGM) when cooler temperatures and greater aridity were thought to have forced the forests into large remnant patches (Figure 3; Maley and Brénac, 1998). Maley and Brénac (1998) also identify ‘sylvigene cycles’ in the vegetation history, defined as repeated successional changes on an approximately 2000-year recurrence interval which may coincide with the Dansgaard–Oeschger cycles observed in the ice sheet record. The record at Barombi Mbo has recently been subject to considerable further analysis employing a numerical biomization method that reveals more detail about the vegetation and climate changes (Lebamba et al., 2010). This method indicates that open savanna formations were never extensive in the basin and that patches of grassland and deciduous woodland, at their most developed during Heinrich event 1, were more likely enclosed within the forest in the form of a mosaic.

Meanwhile, at Lake Bosumtwi in Ghana, a prolonged lake low stand does appear to coincide with the disappearance of rainforest taxa and their replacement with vegetation with greater montane affinities (Maley, 1991) around the time of

Figure 3 Vegetation changes in the African tropical forest biome as indicated from pollen analysis at Lake Barombi Mbo, Cameroon (courtesy of J Maley).

the LGM. This is supplemented by geochemical and geomorphological evidence that further suggests a return to drier conditions at the time of the Northern Hemisphere Younger Dryas oscillation (Shanahan et al., 2006, 2008). Only marginally drier LGM conditions are recorded at Ngamakala in the Congo basin (Elenga et al., 1994), and here, rainforest taxa remain very prominent in the sequence. Marret et al. (2001) note that these drier conditions may have ended abruptly by 13 000 cal years BP because pollen and other evidence from the offshore sediments of the Congo River fan suggest a dramatic increase in discharge at this time. The importance of these various observations is twofold. First, vegetation changes, as indicated by the pollen record, are more complex than can be explained by the simple retreat of rainforest in response to a drier and cooler LGM. Second, on the basis of the available paleoenvironmental proxies, there is conflicting evidence as to the status of rainforest around the time of the LGM; it may have been entirely replaced by savanna in some localities but appears to have survived, albeit in variable forms, in others. There is evidence from ocean sediments off Gabon, western equatorial Africa, of a weakening of the monsoon system brought about by lower sea surface temperatures in the tropical Atlantic (Kim et al., 2010). Anhuf et al. (2006) argue that tropical forest in Africa was reduced in extent by an estimated 84% in response to increased aridity. Accordingly, unlike in South America, the refugium hypothesis still cannot be rejected as a model of vegetation change in the late Quaternary for the African lowland tropics, even if it does not offer a comprehensive explanation of patterns of diversity and endemism.

The Afromontane Region

The cooler conditions at higher altitudes have proved more conducive to the accumulation of pollen-rich organic sediments and, indeed, provided the first Quaternary paleoecological

reconstructions in tropical Africa (Coetzee, 1967). Nevertheless, the dynamics of the afromontane flora and, in particular, the occurrence of glacial aridity and the existence of Quaternary lowland forest refugia in the mountains have been the subject of considerable debate. Significant evidence in this regard has recently emerged from sites in Central East Africa (Jolly et al., 1997; Marchant and Taylor, 1998; Marchant et al., 1997; Rucina et al., 2009; Street-Perrott et al., 2007) and also from Lake Tana in Ethiopia (Lamb et al., 2007).

The review by Jolly et al. (1997) remains significant because it synthesizes the late Quaternary paleoenvironmental implications of several sites within a relatively small geographical area and, in so doing, offers a more reliable reconstruction than the usual single-site pollen analyses. Although the number of published paleoecological studies in the afromontane region as a whole has increased, many biogeographical questions remain unanswered. For example, did the region act as a glacial refugium for lowland taxa and did the forests of tropical Africa respond to change as homogeneous units, or were there differences in response times resulting in the development of unique and non-analog communities? The so-called inter-lacustrine highlands of Central Africa offer the possibility of addressing such issues, and Jolly and coworkers have successfully explored these issues using six radiocarbon-dated pollen sequences drawn from five sites in Uganda, Burundi, and Rwanda, ranging in age from around 40 000 cal years BP to 'modern.' The LGM emerges as a period characterized by relatively xerophytic ericaceous scrub and grassland that, in at least one instance, is suggestive of a treeless landscape. The authors make no direct paleoclimatic reconstructions, but clearly, such conditions are consistent with a cooler and drier climate at the time. As for a refuge for lowland taxa, the pollen data neither support nor refute the existence of the major East-Central Africa refugium proposed by Colyn et al. (1991).

Two sites in Tanzania – Dama Swamp, Iringa (Mumbi et al., 2008), and Deva-Deva (Figure 4; Finch et al., 2009) from

Figure 4 Deva-Deva swamp in the Uluguru Mountains of Tanzania, a late Pleistocene record from within a biodiversity hotspot (photo courtesy of J Finch).

within the biodiversity hotspot of the Eastern Arc mountains – also help cast light on the validity of the refugium hypothesis. The data suggest relative environmental stability in this region over the LGM interval, although there are indications of some changes in forest composition, perhaps in response to marginally drier climates.

Based on evidence from a site on Mount Kenya, [Rucina et al. \(2009\)](#) suggest that the LGM may have actually been characterized by somewhat greater moisture availability than today but that the vegetation assemblage was a hybrid of higher and lower altitude elements. The indication is that, rather than a simplistic shift of vegetation belts to higher and lower elevations in response to late Quaternary climate change, communities dynamically adjusted, assembling and reassembling as individual species migrated. It seems that vegetation belts did not shift elevations as intact units in response to changes in conditions but rather new associations formed as species reacted individually to variations in climate. Other wetlands on Mount Kenya have provided valuable pollen and associated multiproxy evidence of change in the afro-montane region ([Street-Perrott et al., 2007](#)) in response to precipitation and temperature changes. At Lake Tana in north-west Ethiopia, paleoecological and other evidence suggest that the lake dried out around the time of Heinrich event 1 (post-18 700 cal years BP to ca. 15 100 cal years BP; [Lamb et al., 2007](#)). Certainly, changes in montane forest composition reflecting adjustments to climate variation (and, no doubt, atmospheric chemistry) are also apparent throughout the later Pleistocene in many of the afro-montane sequences considered.

Savanna Woodlands and Grasslands

The savanna biome of Africa, the most spatially extensive complex of vegetation formations on the modern continent, is also significantly understudied from the perspective of the late Pleistocene pollen record. While climate, in concert with fire, is a major driver of vegetation in this biome, the involvement of humans in shaping the vegetation pattern over extended periods also needs to be considered ([Meadows, 1996](#)). Longer sedimentary sequences have been retrieved

from wetland sites in Zambia ([Livingstone, 1971](#)) and South Africa (Wonderkrater, Equus Cave, the Eastern Free State, and Pretoria Salt Pan: [Scott, 1982, 1987, 1989, 1999; Scott et al., 2008](#), respectively) and also from Madagascar ([Gasse and van Campo, 1998](#)). These are supplemented by long lacustrine sequences from Lake Tanganyika ([Tierney et al., 2010; Vincens, 1991, 1993](#)), Lake Albert ([Beuning et al., 1997](#)), Lake Masoko ([Vincens et al., 2007](#)), Lake Rukwa ([Vincens et al., 2005](#)), and Lake Malawi ([Beuning et al., 2010; DeBusk, 1998](#)). The simplistic view of a cooler and drier LGM becomes even more difficult to uphold in light of these records, although [Gasse et al. \(2008\)](#) have recently comprehensively reviewed palaeoenvironmental evidence across the African tropics and concluded that the LGM was indeed ‘generally’ drier. Certainly, and uncontroversially, cooler LGM conditions are widely apparent in the records, but the moisture signal appears to be complex, both spatially and temporally. Evidence of greater aridity at the time of the LGM is definitively indicated at several localities, including at least some of the Rift Valley lakes. Pollen evidence from two cores from the southern part of Lake Tanganyika ([Vincens, 1991, 1993](#)) reveals changes in vegetation patterns related to climatic fluctuations from around 27 000 cal years BP onward. The LGM here is characterized by greater abundance of afro-montane vegetation and a correspondingly lower percent of pollen, indicative of humid conditions ([Vincens, 1991, 1993](#)). Around this time, open and poorly diversified savanna woodland and C_4 grassland prevailed at low and mid-altitudes, with local patches of montane forest including *Podocarpus* spp. indicating cooler and drier climatic conditions than today, with frost during the night at low altitude. Pollen data are supplemented by the molecular analyses of [Tierney et al. \(2010\)](#) who note that greater LGM aridity may further have been associated with a dual (i.e., two short rainy seasons) annual precipitation regime but that the role of lowered CO_2 concentrations in favoring C_4 grasslands also needs to be considered. For the catchments of Lake Malawi and Lake Masoko, on the other hand, the pollen and sedimentological records suggest that, following warmer and more arid conditions from around 26 000–34 000 cal years BP, the LGM was characterized by increased pollen frequencies of montane elements and the aridity that typified this period elsewhere in the tropics did not prevail here ([DeBusk, 1998; Garcin et al., 2006a,b](#)). Indeed, DeBusk goes as far as to suggest that the relatively cool and moist late Pleistocene conditions may have facilitated the interchange of biota between the highlands of east and west Africa along the uplands of the Zaire–Zambezi watershed. These conclusions are to some extent supported by those based on more recently cored sediments in Lake Malawi, where [Beuning et al. \(2010\)](#) suggest relatively minor LGM impacts on vegetation by comparison with other periods earlier in the latest glacial that arose out of what they term ‘megadroughts.’

The savannas of southern Africa do appear to have been subject to lower moisture availability around the time of the LGM. [Scott et al. \(2008\)](#) review late Quaternary environments in this region. For example, around the Tswaing Crater ([Figure 5](#)), [Scott \(1999\)](#) documents cooler and drier conditions associated with the lowering of vegetation belts by up to 1000 m, as well as changes in the relative abundance of C_3 and C_4 grasses ([Scott, 2002](#)), again likely in response to lower carbon dioxide concentrations. [Finch and Hill \(2008\)](#) infer

Figure 5 The Tswaing Crater, northeast of Pretoria, South Africa, and the locality of one of the longest Quaternary terrestrial sediment sequences in Africa. Photo courtesy of the Hartbeespoort Radio Observatory (www.hartrao.ac.za/other/tswaing/tswaing.html).

greater aridity around 21 ka at the Mfabeni Peatland, and coastal forests are thought to have retreated along the Maputaland plain around that time. The first real indications of Angolan vegetation response to late Quaternary climate dynamics have recently become available from a marine core off the west coast of Southern Africa (ODP 1078, Dupont and Behling, 2006; Dupont et al., 2008) suggesting that much more open vegetation prevailed during much of the glacial in response to cooler and drier conditions.

Off the east coast of the continent in Madagascar at Lake Tritrivalakely, Gasse, and van Campo (1998) outline a cool and dry LGM, although these conditions appear to have terminated abruptly at around 17 000 cal years BP with significantly increased moisture availability, a change that may have preceded the equivalent in the Northern Hemisphere by as much as 2000 years.

In summary, late Pleistocene temperature signals in the savannas of Africa are relatively wellresolved, but the precipitation and evaporation trends have proved much more difficult to reconstruct. The problem of reconstructing rainfall amounts and seasonality is no doubt exacerbated by the effect of reduced atmospheric carbon dioxide concentrations, especially in this biome, since woodland and grassland dynamics appear to be particularly sensitive to such changes (Bond et al., 2003) and there are clear advantages for C_4 grasses under lower partial pressures of CO_2 (Ehleringer et al., 1997).

Arid and Semiarid Biomes

Quaternary pollen analysis was developed initially in temperate latitudes, and the sedimentary environments in which pollen typically preserves over time are associated with reducing conditions in permanent or at least seasonal wetlands or in lacustrine sediments. Obviously, such habitats are rare in the arid and semiarid biomes of Africa and palynologists have been forced to seek alternative archives. Even so, the number of records, particularly those extending into the late Pleistocene, is very limited and Elenga et al. (2000) cite only Sossusvlei, in Namibia, and Tibesti, Chad, as sites for which there are LGM records. Both have been interpreted as indicating environments somewhat cooler than the present day with even greater aridity. Subsequent sedimentological studies, however,

from both Namibia (Stuut et al., 2002) and Tibesti (Maley, 2000), indicate that even considering the effect of reduced potential evaporation, these regions may have experienced increased precipitation during the LGM. In Namibia, additional insight can be obtained from pollen assemblages derived from marine records that have been obtained off the southwest African coast (Shi et al., 2000, 2001). Marine core GeoB 1023–5 is from a site off the Cunene River mouth at around latitude 17° S and yields information on the dynamics of northern Namib Desert vegetation from around 21 000 cal years BP onward (Shi et al., 2000). The pollen spectra from this core not only indicate the prominence of desert vegetation but also show increases in semiarid scrub, exemplified by higher *Stoebe*-type pollen frequencies as well as the presence of certain elements of the fynbos flora (e.g., *Restionaceae*, *Ericaceae*) that are associated with wetter conditions and increased winter rainfall which presently prevails further south. The presence of *Stoebe*-type pollen in the region, rather than being the result of long distance transport by stronger winds (Stuut et al., 2002), is corroborated by pollen recovered from hyrax middens in the Brandberg Massif (21° S), which show high levels of this pollen in samples dated to 21 100 and 35 000 cal years BP (Scott et al., 2004). A longer temporal perspective, up to 135 000 years, is provided by another core in the region, GeoB-1711-4 off the central Namibian coast (23° S) (Shi et al., 2001). This record indicates several periods in the late Pleistocene during which vegetation changes along the western margin of Southern Africa conform to a general pattern of increased glacial humidity and interglacial aridification; this pattern has been attributed to equatorward migrations of the westerly storm tracks as a response to increased Antarctic sea-ice extents (cf. Chase and Meadows, 2007; Stuut and Lamy, 2004; Stuut et al., 2004; van Zinderen Bakker, 1976). Dupont and Behling (2006) provide supplementary evidence for terrestrial vegetation change in semiarid southwestern Africa from ODP 1078 that reveals a cold and dry LGM was succeeded by cool and wet conditions during Heinrich event 1.

Mediterranean-Climate Regions

The distinctive climate of regions with warm, dry summers alternating with cool, wet winters is characteristic of the Mediterranean regions of North Africa and of the southwestern part of the continent and is associated with species-rich vegetation formations dominated by evergreen sclerophyllous shrubs. Virtually, nothing is known about the late Pleistocene development of this vegetation type in North Africa. Elenga et al. (2000) document no pollen records for the LGM in this region, but more recent work has cast some light on the situation. In Morocco, Lamb et al. (1989) do provide a pollen record that extends back to around the time of, or at least shortly after, the LGM from Lake Tigalmamine in the Middle Atlas Mountains, and there is a more recent and longer core from Lake Ifrah (Rhouijati et al., 2010). The pollen spectra in basal samples of the 21-m Tigalmamine core are very strongly dominated by grasses, chenopods, and *Artemisia*, resulting in what is referred to as steppe vegetation under climatic conditions that, on this basis, appear to have been too cold and arid to support tree growth at the time. At Lake Ifrah, glacial climates

(29 ka onward) appear to have been colder and generally drier than today with the most intense aridity around 19.5–12 ka (Rhoujjati et al., 2010). Nevertheless, there is evidence for periods of greater moisture availability in the Lake Ifrah record and, indeed, some tree taxa, specifically *Cedrus*, appear to have survived in scattered refugia in the region during glacial times (Cheddadi et al., 2009). The paleoecological evidence thus favors the existence of drier as well as cooler climates for the glacial. Tzedakis (2007) suggests that the contradictory pollen and lake level records for the region during the coldest parts of the last glacial may be reconcilable. Either there was indeed less rainfall associated with increased cloudiness and reduced evapotranspiration or there were increased seasonal contrasts, with colder and wetter winters (more snow) and a more pronounced summer drought. In regard to the Late Glacial, the invasion of evergreen oak (*Quercus* spp.) onto the steppes around Lake Tigalmamine signifies that climate warming was underway by 14 ka and coincided with lower lake levels, and the record at Lake Ifrah is consistent with this reconstruction (Rhoujjati et al., 2010). However, the open, treeless steppe vegetation again dominated around the time of the Younger Dryas (Lamb et al., 1989), and conditions were never sufficiently warm and moist for woodland to prevail around this site until well into the Holocene.

At the other end of the continent, in the southwestern Cape, the late Pleistocene pollen record has been supplemented with records obtained from hyrax (*Procapra capensis*) middens. These unusual archives are revealing themselves to be remarkably sensitive paleoenvironmental archives (Chase et al., 2011; Meadows et al., 2010). The potential of these deposits was first recognized in the 1990s when Scott (1994) – and subsequently Scott and Vogel (2000) – explored pollen sequences in hyrax middens, revealing vegetation changes in terms of both species composition and the relative importance of C_4 , C_3 , and CAM plants from around 20 000 cal years BP onward at Pakhuis in the Cederberg mountains at around 32° S. That work has since been supplemented by several more detailed palynological and stable isotope studies on middens (Chase et al., 2011; Meadows et al., 2010; Scott and Woodborne, 2007a,b) that reveal late Pleistocene environmental dynamics in this region. Changes in plant species composition suggest a lowering of vegetation belts around the time of the LGM, with increased proportions of upland taxa in the record in response to lower temperatures and what is interpreted to be somewhat greater aridity. The stable carbon isotope signals for this interval show no enrichment, as would be expected during a period of lower atmospheric carbon dioxide, and indicate that winter rainfall persisted in the region throughout the interval in question and in fact may have been more effective than in the present day. That such winter rainfall may have been more effective, through a combination of increased annual amounts and a reduction in evaporation rates, is supported by pollen and charcoal data from Elands Bay Cave, a coastal site less than 100 km west of the Cederberg, where there are substantially higher frequencies of afro-montane vegetation indicators than occur today during at least some intervals of the last glacial (Chase and Meadows, 2007; Parkington et al., 2000). The highest resolution record of last glacial–interglacial transition environments obtained thus far comes from a large hyrax midden in the Cederberg (Chase et al., 2011) where a

stable isotope signal of available moisture provides unequivocal evidence of the occurrence of a well-defined, cold, and dry period coincident with the Younger Dryas and pointing to the influence of Northern Hemisphere drivers of climate even as far south as 32° S after Heinrich event 1.

Further south, in the Cape Peninsula region, several pollen cores have been recovered from Rietvlei and the Cape Flats (Schalke, 1973). Pollen from these cores shows significant differences between what has been interpreted as Holocene deposits and those dating to the last glacial. Although many of the ages from older deposits are, arguably, infinite, ranging from $40\,100 \pm 3000$ – $47\,960 \pm 2500$ ^{14}C years BP, adjacent sediments with similar pollen spectra date to $32\,770 \pm 1000$ – $34\,660 \pm 900$ ^{14}C years BP ($\sim 37\,500$ – $39\,500$ cal years BP). Pollen spectra from these deposits are very similar to spectra from modern wetlands adjacent to the humid forests of the south coast, suggesting significantly more effective and less seasonal precipitation during periods of the last glacial cycle.

Higher rainfall for the winter rainfall zone of South Africa appears to be out of phase with vegetation indicators elsewhere in southern Africa at this time and is especially interesting given the implications of lower atmospheric carbon dioxide levels which should reduce plant available moisture.

Conclusions

The paucity of the pollen record for the late Pleistocene of Africa certainly hampers the reliability, if not the validity, of any summary conclusions regarding the nature of vegetation change and its causes. As Hessler et al. (2010) state, there is clearly a need for more records, especially from the northern equatorial tropics of Africa where there are “...no records at all” (p. 2895). Not surprisingly, the strongest paleoenvironmental signal emanating from pollen sequences of the late Pleistocene is that of lower temperatures, and coupled with strong evidence for increased aridity in many biomes, this had the effect of limiting biomass through reduction in forest and woodland taxa. Thus, the tropical rainforests of West and Central Africa were reduced in extent through encroachment of montane vegetation shifting in altitude and of savanna and grassland vegetation shifting in latitude. The expansion of the deserts is less obvious in the pollen record, but this is perhaps a consequence of gaps in the data rather than any resilience on the part of the vegetation to climate change. The extent to which the vegetation changes were a result of climate change, that is, temperature and precipitation reduction, remains a key and, as yet, largely unresolved issue. The complicating issue of atmospheric chemistry changes remains unresolved, for example, Jolly and Haxeltine (1997) use a process-based vegetation model to argue that substantial variation in the vegetation of the East African mountains is possible as a consequence of lowering atmospheric carbon dioxide concentrations and that estimates of LGM cooling (by 4 °C) and aridity (30% lower precipitation) in this biome may both have been overestimated.

Nevertheless, the vegetation changes inferred from pollen analysis are both substantial and in line with major global changes in glaciation and insolation regimes as shown by Jolly et al. (1998). It appears that the same forcing mechanisms that have defined global climate change throughout the

Quaternary (e.g., Milankovitch cycles of orbital variation, polar ice development, oceanic circulation patterns) have been the key drivers behind the described patterns of vegetation change. Across the continent, however, these forcing mechanisms have played a varying role and have had various levels of impact as a function of their particular dynamics and sphere of influence. It is, therefore, too simplistic to argue that glacial and interglacial cycles correspond to cycles of aridity and humidity, respectively. In tropical monsoon-influenced regions, decreased temperatures and a less-active global hydrological system during glacial periods have apparently resulted generally in increased aridity. In temperate regions, however, some evidence does exist that increased hemispheric temperature gradients and polar ice extents have resulted in invigorated westerly systems, and increases in precipitation in the lower mid-latitudes and perhaps even in the subtropics. Each of these cycles operates at a different frequency, with the interplay set upon the backdrop of orbital and ice-forced 100-ka cycles of depressed temperatures and reduced atmospheric CO₂. The amalgam is not easy to decipher.

The studies presented here define a stage in an ongoing process to better understand the relationship between changing African climates and ecology. This knowledge is especially critical when considering our attempts to understand the future effects of potential anthropogenic impacts on climate and the global system as a whole. If management and mitigation of human influence are to be best directed, it is vital that we develop an understanding of the natural variation of the systems being considered, and a sense of causality, so that the direction of change can be best predicted.

Introduction

The vegetation of the Australasian region reflects the major changes that have taken place in its geographical position, and hence climate, through the Cenozoic Era, including a long period of isolation from other parts of the world. Prior to this time, the whole of Australasia was part of the southern land mass of Gondwana, much of which was dominated by a wet temperate to subtropical flora that today is largely restricted to cool to warm temperate rainforests of New Zealand and south-eastern Australia, extending, in small patches, along the eastern Australian coastal ranges to tropical north-eastern Australia and New Guinea (Hill, 1994). After separation from Gondwanaland, New Zealand remained largely within temperate latitudes but Australia has progressively moved northward into warmer and drier latitudes. This period of isolation resulted in the development of the unique nature of Australian vegetation, characterized by a high degree of sclerophyll (the development of thickened, hardened foliage that resists loss of moisture). There are extensive xerophytic woodlands and shrublands, with *Acacia* as a major dominant, within the heart of the continent and mainly *Eucalyptus*-dominated sclerophyll forest, woodland, and shrubland on the wetter periphery (Kershaw et al., 2000) (Figure 1).

The continued northward movement of Australia into tropical latitudes has brought it into close proximity to the tropical rainforest environments of Southeast Asia. Although there has been little faunal mixing between the two regions, as evidenced by the well-established Wallace's Line, there has been significant immigration of rainforest taxa into New Guinea within the last 15 Ma or so as indicated by the characteristically Southeast Asian composition of the lowland rainforest. However, the extent of invasion of rainforest taxa into Australia is debated (Truswell et al., 1987; Whiffin, 2002; Sniderman and Jordan, 2011). The situation is complicated by a possible recycling of Gondwanan taxa into Australia via India and Southeast Asia and by the nature of present-day small drier rainforest patches (tropical deciduous broadleaf forest or monsoon forest) that show affinities with more tropical dry forests on other Gondwanan continents (Morley, 2002).

The significance of this history to late Pleistocene vegetation, as constructed from pollen records, is that, unlike other parts of the world that have not experienced this degree of isolation, there has been minimal input of plants that have evolved elsewhere, and this may have influenced specific responses of the indigenous vegetation to Quaternary climate fluctuations. In the case of New Zealand, this isolation continued through the late Pleistocene. Isolation was broken in Australia within the period of interest with the arrival of people by at least 45 ka (O'Connell and Allen, 2004; here and elsewhere 'ka' refers to 'kiloyears' or thousands of years before present) but people were absent from New Zealand until about the last 1 ka (Wilmshurst et al., 2008). A focus on the

late Pleistocene within the Australasian region as a whole, therefore, allows some assessment of the relative influences of climate and people on the regional vegetation, as evidenced in the pollen record.

Nature of the Data

The vast majority of pollen records within the region are restricted to the Holocene interval with few extending far into the Pleistocene. This is partly a result of a lack of suitable sites for sediment accumulation within a continent dominated by tectonically old land surfaces combined with dry or climatically very variable conditions that are not conducive to pollen preservation. The major exceptions to this pattern are found along the eastern seaboard of Australia, in addition to New Guinea and New Zealand, where all terrestrial records covering at least the whole of the late Pleistocene are located. Both New Guinea and New Zealand are volcanically and tectonically active and have experienced some glaciation while recent volcanic activity has occurred within limited parts of north-eastern and south-eastern Australia. Minor tectonism and glaciation is evident in the highlands of south-eastern Australia. Even in these areas, though, the majority of pollen records are discontinuous.

Complementing and extending the terrestrial pollen data are records from marine cores. These are generally more continuous, have the major advantage of being supported by chronologies derived from associated oxygen isotope records, and can record vegetation from drier areas where no terrestrial sedimentary records exist. They generally lack the resolution of terrestrial sedimentary records due to slower sedimentation rates and some surface sediment mixing and the source of the pollen and its mechanisms of transport to a site are more difficult to determine without extensive modern pollen sampling.

Additional limitations to palynology in Australia are the relative representation and taxonomic resolution of critical taxa. The dominant of more arid vegetation, *Acacia*, is notoriously underrepresented due to relatively poor pollen production and dispersal. Other major taxa such as *Eucalyptus*, Poaceae, Asteraceae, and Chenopodiaceae can seldom be identified beyond the genus or family level despite containing a large number of species. However, the restriction of late Pleistocene records largely to wetter areas that can support a variety of rainforest as well as sclerophyll communities associated with steep rainfall and/or temperature gradients, provides good pollen sensitivity to environmental forcing.

Major features of records, covering most or all of the late Pleistocene for different regions, are selected here to provide a framework of vegetation change within the Australasian region (Figure 1). Charcoal values, where available, are presented with pollen data to provide an indication of the biomass

Figure 1 Generalized present day vegetation cover of the Australasian region (Kershaw et al., 2000) and location of selected late Pleistocene pollen records: 1 (Okarito Pakahi), 2 (DSDP Site 594), 3 (Lake Tangonge), 4 (Lake George), 5 (Core GC-3), 6 (Lake Selina), 7 (Caledonia Fen), 8 (Lake Wangoom), 9 (core E-55-6), 10 (Lynch's Crater), 11 (Aru Sea core MD982175), 12 (North Australian Basin core MD982167), 13 (ODP Site 820).

burning that is an important characteristic of Australian environments. The Holocene component of each record is included to provide a recent reference for assessment of degree and direction of past changes while some indication of the extent of variation in vegetation within the last glacial cycle can be visualized from comparison of reconstructed Holocene vegetation (Figure 1) and the estimated vegetation cover at the extreme of the glacial interval, the Last Glacial Maximum (LGM) (Figure 2). The previous glacial cycle in these records, where available, is also included to allow assessment of the degree to which the last glacial cycle is representative of glacial-interglacial cyclicity and to allow a better indication of climate versus human influences in those records where human activity within the last cycle is likely. Marine isotope records that provide largely a measure of Northern Hemisphere ice volume, and regional insolation curves (Berger and Loutre, 1991), are included with pollen diagrams, where appropriate, to allow assessment of Northern and Southern Hemisphere climate forcing influences on the vegetation.

New Zealand

Long marine pollen records from off the eastern coast of New Zealand provide a broad picture of the New Zealand vegetation and, from comparison with associated marine oxygen isotope records, suggest major Northern Hemisphere insolation and ice volume forcing with expansion of forest vegetation during warm and wet interglacials and replacement, to varying degrees, by shrubland and steppe-grassland during

cooler and drier glacial intervals (Heusser and van de Geer, 1994; Mildenhall, 2003).

Indicative patterns of vegetation and climate change for much of the country during the last glacial cycle are provided by the glacial moraine-impounded peat bog of Okarito Pakahi, the only terrestrial record to continuously cover the late Pleistocene interval (Vandergoes et al., 2005) (Figure 3). This record is complemented by the generalized DSDP site 594 marine pollen record that also provides corroborative evidence for the chronology derived from radiocarbon, thermoluminescence, and tephra dates on Okarito Pakahi (Figure 3). High temperatures during the interglacial intervals of MIS 5e and 1, as well as interstadials MIS 5c and 5a, are indicated by high representation of pollen from lowland podocarp-hardwood rainforest, dominated by the podocarp *Dacrydium cupressinum*. This pattern supports the global temperature picture except that the last interglacial does not appear to achieve the degree of climatic amelioration experienced in the Holocene, and the vegetation response was as great in the interstadials of MIS 5c and 5a as it was in MIS 5e. The glacial intervals of MIS 6 and MIS 4–2 are characterized by the significant presence of pollen from herbs (largely Poaceae with notable Asteraceae) apart from the early part of MIS 3, indicating more open vegetation. The generally very high values of pollen from montane-submontane shrubs in the Okarito Pakahi record indicate temperatures substantially cooler than today. The reduced percentages of shrubs during MIS 6 are the result of high values of pollen for the cool temperature rainforest tree/shrub *Nothofagus* subgenus *Fuscospora*. The current absence of this taxon within the vegetation of this area is not a

Figure 2 Inferred vegetation cover of the Australasian region at the Last Glacial Maximum (Kershaw et al., 2000). Pollen sites are the same as those in Figure 1.

feature of the island as a whole and has not been satisfactorily explained (e.g., Leschen et al., 2008).

A marked deviation from the Northern Hemisphere pattern is the early entry into maximum glacial conditions as indicated by a sharp rise in herb pollen values, perhaps about 30 ka as opposed to about 25 ka globally. This is suggested to be the result of forcing by regional Southern Hemisphere insolation preceding that of the Northern Hemisphere (Vandergoes et al., 2005). The subsequent maximum in Southern Hemisphere insolation, around 20 ka, may also have been responsible for early deglaciation in the region.

The northernmost part of New Zealand, Northland, is considered to have differed significantly in the nature of vegetation changes to the remainder of New Zealand in that, away from the direct influence of glaciation, precipitation, and also fire have been major controlling factors (Newnham, 1999). The difficulty of obtaining a continuous pollen sequence, though, led to debate over the degree to which forest persisted in this region during the last glacial interval. Some resolution of this question was provided by the construction of a lowland record from the dune-dammed Lake Tangonge (Elliot et al., 2005) (Figure 3). This record is considered to extend back to MIS 4 although the chronology beyond the limit of radiocarbon dating is uncertain. As through much of New Zealand, conifer-hardwood forest dominated by *Dacrydium cupressinum* is

currently dominant but is distinguished by the addition of the subtropical emergent araucarian conifer, *Agathis*, while *Nothofagus* subg. *Fuscospora* cool temperate forest is almost absent. The record suggests the maintenance of a complete forest cover through the last glacial interval with conifer-hardwood forest as a major component. This component was greatest during what is considered to be MIS 4. Conditions were wet but cool, as indicated by low *Agathis* values and the absence of the other major warm taxon, *Ascarina*. The significant representation of both these taxa in the early part of MIS 3 indicates at least as wet but significantly warmer conditions while the subsequent demise of the latter genus and increase in the former genus between about 43 and 30 ka suggests the development of greater seasonality with drier summers and cooler winters (Elliot et al., 2005). Full glacial conditions are indicated from the early date of around 30 ka by the expansion of *Nothofagus* that, combined with evidence for frequent burning, suggests a cool, drier and probably windier climate. The peaks in burning and Poaceae suggest that driest conditions occurred during termination of the Pleistocene. However, the limited dating control opens a possibility that there is a gap in the record here and that much of MIS 2 experienced dry conditions with some disruption of the forest cover. The vegetation of the Holocene is remarkably similar to that of early MIS 3.

Figure 3 Variation in relative abundance of major or indicator taxa and taxon groups in relation to a dry land pollen sum for selected New Zealand pollen records compared to the DSDP 594 benthic $\delta^{18}\text{O}$ record, the summer insolation curve for 40°S and the marine isotope stratigraphy of [Martinson et al. \(1987\)](#). Charcoal values, expressed as particles/cc $\times 1000$, are also included for one site, Lake Tangonge, as a measure of past biomass burning.

The Northland region records uncertainties, both in terms of continuity and chronology as well as paleoenvironmental reconstruction. These issues are being addressed by multiproxy studies on volcanic maars that are known to cover the last 30 ka but have the potential to extend back continuously to at least 245 ka ([Molloy et al., 2009](#)). A combination of radiocarbon and tephrochronological ages on sediments from Onepoto maar, south of Lake Tangonge, demonstrate the continued occurrence of a forest cover dominated by *Nothofagus* from at least 30 ka to ~ 14 ka with some grassland and herb-field present during the dry, windy height of the last glacial interval, dated here between about 28.5 and 18 ka ([Augustinus et al., 2011](#)). Climatic amelioration from 18 to 14 ka is marked by an increase to dominance of lowland podocarp forest, especially *Dacrydium cupressinum*, and, after some Late Glacial perturbations, the presence of *Ascarina* indicates maximum Holocene temperatures by about 10.5 ka.

South-Eastern Australia

The controversially dated pollen record from Lake George ([Singh and Geissler, 1985](#)) suggested marked changes in the vegetation of south-eastern Australia through the middle and late Pleistocene that could be explained largely by Northern Hemisphere orbital and ice volume forcing and this pattern of change has been confirmed recently by a pollen record from core GC-3 on the Tasman Rise (Sander van der Kaars, unpublished). For the last glacial cycle, details of vegetation change, covering much of the landscape variation in more humid areas, are provided by three records: Lake Selina from the formerly glaciated landscape of western Tasmania ([Colhoun et al., 1999](#)), Caledonia Fen from the south-eastern highlands of Victoria ([Kershaw et al., 2007, 2010](#)), and Lake Wangoom from the western plains of Victoria ([Harle et al., 2002](#)) ([Figure 4](#)).

Lake Selina shows many similarities with Okarito Pakahi in its formation as a result of Pleistocene glaciation, and its setting

Figure 4 Variation in relative abundance of major or indicator taxa and taxon groups in relation to a dry land pollen sum for selected pollen records from south-eastern Australia compared with charcoal records from individual sites expressed as percentages of dry land pollen (Lake Selina and Lake Wangoom) and particles per cm^3 (Caledonia Fen), and the marine isotope stratigraphy of [Martinson et al. \(1987\)](#).

within Gondwanan temperate rainforest that experiences high rainfall, in excess of 3000 mm per annum. It differs in that it is at a higher altitude, ~ 500 m.a.s.l., that *Nothofagus* subgenus *Menziesii* (specifically *N. cunninghamii*) is the dominant rainforest element although conifers (largely *Phyllocladus*) are well represented, and in the intrusion of sclerophyll taxa into the vegetation. Although radiocarbon dates suggest that the record probably extends to the beginning of MIS 3, U/Th dates, together with comparison with the marine isotope stratigraphy, led to the conclusion that it covered the whole of the last glacial–interglacial cycle ([Colhoun et al., 1999](#)). Certainly, the pattern of change that is so similar to that at Okarito Pakahi would support this view, although the sclerophyll components of the two rainforest-dominated phases at Selina are very different, with Casuarinaceae pollen prominent in the early stage and *Eucalyptus* pollen in the latter stage. In common with Okarito Pakahi, dominance of rainforest during MIS 5e and the Holocene and the prominence of herbs, together with significant representation of alpine/subalpine shrubs, indicate strong temperature control over the sequence. In contrast to Okarito Pakahi, climatic amelioration during MIS 5e appears to have been much greater than in substages 5c and 5a. Despite the high rainfall, and dominance of rainforest during the interglacial intervals, fire has been a major feature of the environment and fire activity appears to have increased through the record.

Caledonia Fen probably formed within a blocked depression of a tributary of the Caledonia River. It lies at 1300 m.a.s.l. within eucalypt-dominated upper montane forest. It provides a rare glimpse into full last glacial conditions at high altitude ([Kershaw et al., 2007](#)). Age extrapolation to the base of the 20 m sequence on the basis of radiocarbon and optically stimulated luminescence ages higher in the sequence that fall within the last 60 ka suggests a late MIS 6 date for site formation. Using this chronology, the interglacials of MIS 5e and 1 stand out due to their dominance of eucalypt pollen and organic sediment. By contrast, almost the whole of the glacial intervals are dominated by steppe-grassland composed predominantly of Poaceae and Asteraceae, suggesting substantially

reduced temperatures. Reduced precipitation is also indicated by high values of salt-tolerant Chenopodiaceae that are excluded from the pollen sum. Low productivity in the shallow lake during glacial times is demonstrated by the lack of pollen from aquatic taxa, presumably because of ice coverage of the lake through much of each year. However, the record is also characterized by a high level of millennial variability that has yet to be fully analyzed. One substantial deviation from the glacial pattern, where forest development and aquatic productivity almost matched those of the interglacials, was subject to higher resolution study ([Kershaw et al., 2010](#)). The event was placed in early MIS 3 by [Kershaw et al. \(2007\)](#) but subsequent OSL ages suggested an MIS 4 age estimate of 66.8–65.5 ka. The abrupt nature of the event is suggestive of a Dansgaard–Oeschger (D–O) event but the fact that it is singular, appears not to date to a D–O event elsewhere, and is so remote from the presumed North Atlantic trigger, makes such a correlation unlikely and, hence, an interpretation difficult. It is also unusual that this degree of climatic amelioration is not recorded during the interstadials of MIS 5, which may only be recognized by fluctuations within the one remaining rainforest-related taxon in the region, *Podocarpus*, and the sclerophyll conifer, *Callitris*.

The low altitude volcanic crater site of Lake Wangoom, situated within open eucalypt forest or woodland, reflects mainly variation in effective rainfall rather than temperature. The published chronology, based on U/Th dates as well as by comparisons with a shorter marine palynological record ([Harle, 1997](#)) and the marine isotope stratigraphy, suggests that it covers the last two glacial cycles ([Harle et al., 2002](#)). In general terms, interglacials are clearly identified by marked expansion of forest vegetation, while glacials are characterized by steppe-grassland dominated by Poaceae and Asteraceae, but the chronological control is insufficient to identify interstadial and stadial phases with any certainty. An alternative chronology, based on radiocarbon and OSL dates within the upper part of record, suggests only one cycle with a major interstadial in MIS 3 achieving forest development at least equivalent to those of the Holocene and what would be the latter part

of MIS 5 at the base. Support for this chronology may be the lack of response of Casuarinaceae in the middle forest phase, perhaps suggesting a different climate scenario. Under either chronology, forest development in the Holocene may be less than expected by Milankovitch forcing in that grass pollen is highly represented and there is a much smaller proportion of pollen from wetter rainforest (predominantly *Nothofagus*) and wet sclerophyll forest (*Pomaderris*) elements. This pattern may be the result of either an overall trend to drier conditions or human impact as indicated by generally highest charcoal values for the record within MIS 3/2, using either timescale.

Northern Australia

For many years, the pollen record of Lynch's Crater from the Atherton volcanic province within the humid tropics of north-east Queensland provided the only basis for reconstruction of late Pleistocene vegetation and environments in northern Australia (Kershaw, 1985). However, in recent years, some indication of variation within the region has been provided by the reconstruction of several pollen records from marine sediments taken from the seas between Australia and Indonesia (Kershaw and van der Kaars, 2012). Two such records (MD982175 and MD982167), which relate to different northern Australian landscapes, are presented in Figure 5. In addition, a third marine record (ODP Site 820) from off the coast of

the humid tropics of north-eastern Australia is included to provide a comparison with Lynch's Crater (Figure 6).

The MD982175 Aru Sea core lies close to both New Guinea and the Sahul continental shelf, an extensive region that connected northern Australia to New Guinea during low sea-level phases. The pollen record covers about the last 155 ka, based on comparison with the associated oxygen isotope record (Beaufort et al., 2010). This record shows a dominance of rainforest pollen during the interglacial periods of MIS 5e and 1, as well as in the interstadials of MIS 5c and 5a (Kershaw and van der Kaars, 2012). Sclerophyll taxa increase slightly during the MIS 5 stadials and substantially during the glacial intervals of MIS 6 and 4–2 although the responses of sclerophyll trees (predominantly *Eucalyptus*) and herbs (almost entirely Poaceae) are different, based on their fossil pollen records. The pattern suggests that glacial climates were generally drier than those of the interglacials, probably the result of a general reduction in the influence of the Asian–Australian monsoon that is considered to be largely in phase with Northern Hemisphere radiation and ice volume forcing (Miller et al., 2005). However, regional influences such as low latitude southern insolation and the drying of the extensive continental shelves have had some importance. The degree of apparent rainforest reduction during glacials may also be exaggerated as a result of increased proximity of Australian eucalypt woodland to the site with the exposure and consequent occupation by vegetation of the Sahul shelf. Charcoal levels are variable and difficult to decipher in relation to changes in vegetation.

Figure 5 Variation in relative abundance of major or indicator taxa and taxon groups in relation to a dry land pollen sum for selected pollen records from northern Australasia (Aru Sea Core MD982175 and North Australia Basin Core MD982167) compared with charcoal/pollen ratios from each site, the marine isotope stratigraphy of Martinson et al. (1987), and the summer insolation curve for 20° S.

Figure 6 Variation in relative abundance of major or indicator taxa and taxon groups in relation to a dry land pollen sum for selected pollen records from north-eastern Australia (Lynch's Crater and ODP Site 820) compared with charcoal values for each site expressed as particles/cm³, the planktonic $\delta^{18}O$ curve from ODP Site 820, and the marine isotope stratigraphy of [Martinson et al. \(1987\)](#).

However, the beginning of a sustained increase in burning around 40 ka may have been ecologically significant in bringing about the decline in the regional dominant plant family of Southeast Asian lowland rainforest, Dipterocarpaceae.

Core MD982167, from the North Australian Basin, lies adjacent to a region of extensive eucalypt savanna vegetation with small patches of dry (monsoonal) rainforest in the Kimberley region. A summary diagram ([Kershaw and van der Kaars, 2012](#)), shown in relation to the chronology derived from an associated oxygen isotope record (Bradley Opdyke, personal communication), shows the predominance of this savanna woodland throughout the last 250 ka. Glacial-interglacial cyclicity is evident in the proportion of tree and shrub pollen (largely *Eucalyptus*) relative to herb pollen (essentially Poaceae). However, superimposed on this cyclicity is a strong 20 ka Southern Hemisphere precessional frequency. It is hypothesized that this is a monsoon signal emanating from the Indian Ocean, rather than a push from the Asian monsoon winds, with precessionally induced sea surface temperatures controlling much of the precipitation variation. Divorced from these patterns is a sharp increase in charcoal from the beginning of MIS 5 and a sharp reduction in rainforest pollen around 45 ka, just prior to a sustained increase in charcoal values.

In north-eastern Australia, the ODP site 820 record is accompanied by an isotope curve from the foraminiferan *Globigerinoides ruber* produced by [Peerdeman et al. \(1993\)](#). Although there is some debate over the degree of continuity of this core, major features such as the MIS 6/5 boundary are clear and have been used to assist in establishing a chronology for the Lynch's Crater record beyond the limit of radiocarbon dating ([Moss and Kershaw, 2000](#)). This chronology has recently been substantiated by direct OSL dating of the Lynch's Crater record ([Rieser and Wust, 2010](#)). Both records cover about the last

215 ka and reflect variation in the nature and extent of the most extensive patch of tropical rainforest in Australia. Herbs have been omitted from the pollen sums due to very local overrepresentation of Poaceae in the upper part of the Lynch's Crater record.

The record from Lynch's Crater exhibits clear glacial-interglacial cyclicity with pollen from angiosperm-dominated rainforest, which makes up almost entirely the humid tropics rainforest today, peaking during wetter interglacials. However, the Northern Hemisphere signal appears distorted in places, especially during MIS 5 where there is evidence of only one interstadial. Intervening glacial intervals show high values of sclerophyll or savanna woodland pollen. These plant communities surround the modern rainforest, although the pollen signal shows that *Eucalyptus* only became a dominant of this vegetation type in the last glacial period. High values of pollen from rainforest conifers, indicating extensive drier *Araucaria*-dominated rainforest, demonstrate partial replacement of the angiosperm rainforest until about 45 ka ([Turney et al., 2001](#)) when these were totally replaced by sclerophyll vegetation. The sharp and largely sustained increase in charcoal at this time has led to the long-held hypothesis that an increase in burning with the arrival of Aboriginal people resulted in the demise of fire-sensitive *Araucaria* forest and promotion of fire-resistant *Eucalyptus* ([Singh et al., 1981](#)). A similar relationship between *Araucaria* forest, *Eucalyptus*, and charcoal is noted in the ODP Site 820 record at a similar time, but the picture is complicated by an earlier partial reduction in *Araucaria* at the MIS 6/5 boundary that also shows a marked peak in charcoal and some *Eucalyptus* response, at a time before there is any evidence for people on the continent. It has been suggested that the early event was the result of a combination of dry conditions at the very end of MIS 6 and high El Niño/La Niña-Southern Oscillation (ENSO) activity, while the latter was caused by

human impact in combination with ENSO climatic variability (Kershaw et al., 2003). The effect of continued human burning may have retarded final rainforest expansion until about 7 ka, well after the Pleistocene/Holocene boundary.

General Discussion

The illustrated pollen records, covering a wide range of Australasian environments, demonstrate marked and varied responses of vegetation to past environmental forcing. Vegetation variation is regional in character with little evidence of long distance migration, a result, no doubt, of long-term adaptation to particular niches that are maintained in the absence of wholesale disruption that occurs with the development of continental ice sheets. The global influence of Northern Hemisphere insolation and ice volume, so evident in marine isotope records, is most clearly expressed in terrestrial records by temporal vegetation patterns in the most southerly latitudes of the continent where temperature is the dominant variable and in the northern part of Australia where some influence of the Asia monsoon system on precipitation variation is evident.

There is evidence of the superimposition of Southern Hemisphere insolation forcing on the orbital scale in the majority of records, and most particularly in northwestern Australia where the source of monsoon rainfall is predominantly from the surface of the Indian Ocean that has no direct connection to high northern latitudes. A subtle relationship between temperature and precipitation, including seasonal variations, as well as latitudinal movements in the major pressure systems, may have influenced patterns of vegetation change in the mid-latitudes of mainland south-eastern Australia. The suggestion of a distinct warm event at Caledonia Fen at 66 ka may be the result of age uncertainty though a similar event is evident from OSL ages in shorelines of old megalakes in more arid south-eastern Australia (Cohen et al., 2012). Within the latest Pleistocene, well dated records have indicated a Southern Hemisphere influence on the timing of the onset and termination of the coldest part of the last glacial interval, especially in New Zealand.

Some millennial scale variability is evident within the last glacial–interglacial transition but is regionally variable and shows little relationship with features like the Younger Dryas (e.g., Augustinus et al., 2011; Turney et al., 2006) which characterize much of the globe. Before this time-consistent millennial scale variability, as evident elsewhere mainly as D–O events within the last glacial period, is difficult to detect in pollen records, but may be a feature of the Caledonia Fen record (Kershaw et al., 2010) and has been demonstrated to exist within the local pollen and sediments of the Lynch’s Crater record where a teleconnection between Pacific ENSO and North Atlantic D–O cyclicity has been proposed (Turney et al., 2004).

There appears to be little relationship between biomass burning as indicated by charcoal, vegetation, and inferred climate change from the records presented. However, the recent analysis of some 223 sedimentary charcoal records from Australia, many extending into the Pleistocene, strongly suggests that burning has been higher during warmer periods,

including interglacials and D–O interstadials (Mooney et al., 2011).

A feature of several Australian records is a trend toward more sclerophyllous vegetation, generally associated with an increase in burning. A major event is identified around 40–45 ka that, in the absence of a major change in climate at this time and correspondence with earliest archaeological evidence (e.g., O’Connell and Allen, 2004), can, at least in part, be attributed to human burning. However, as indicated most clearly in the ODP Site 820 record, this trend was initiated prior to evidence for the presence of people. Despite the proposal by Singh et al. (1981) that vegetation changes associated with increased burning around 125 000 years ago in the Lake George pollen record were due to Aboriginal activities, and support for increased burning around that time in the northern Australian records presented here, a climatic cause is considered most likely. It has been suggested that the trigger may have been the crossing of a critical threshold in Australia’s movement toward Southeast Asia that constricted water movement through the Indonesian throughflow from the Pacific to Indian Ocean, leading to a build up of warm water forming the West Pacific Warm Pool (Figure 1), and the consequent establishment or intensification of ENSO variability (Isern et al., 1996; Kershaw et al., 2003). This whole scenario may be questioned on the basis of the charcoal analysis by Mooney et al. (2011), who see no systematic change in fire regime through time, including the period of human arrival. However, their analysis extends back only 70 ka and fails to take into account pollen data that allow assessment of the impact of fire, not just its pattern of occurrence.

Introduction

Siberia, which spans all of northern Asia, often invokes timeless images of frozen barrens and vast stretches of snow-covered taiga. However, the modern landscape is relatively young, shaped by late Pleistocene conditions that were much warmer, much colder, and much drier than the present. Soviet scientists, who first described the environmental history of Siberia, mounted multi-disciplinary expeditions focused on exposure of ancient sediments found along major river valleys. Even though the reconstructions themselves were detailed, often combining data from palynological, plant macrofossil, faunal, glacial geological, and geomorphological analyses, the discontinuous depositional nature of fluvial and floodplain deposits limited the paleoenvironmental reconstructions to 'snapshots' in time. Local reconstructions were then correlated to form regional stratigraphic schemes that still shape the descriptions of Quaternary Siberia. More recently, scientists have collected ancient sediments deposited in extant lake basins, which provide continuous records of change that have helped clarify and modify the original interpretations of late Pleistocene landscapes.

This article concentrates on palynological records of northern Siberia, from the arctic islands to the southern taiga ($\sim 80^{\circ}$ – 60° N) and from Bering Strait to the polar Urals ($\sim 170^{\circ}$ W– 65° E; [Figure 1](#)). Today, tundra and forest-tundra are found to the north of $\sim 68^{\circ}$ N, except in areas bordering the Bering Strait where tundra and forest-tundra occur as far south as 60° N. Modern conifer-dominated taiga of Siberia occurs between $\sim 68^{\circ}$ and 50° N. The region is divided into three geographic areas: northeast Siberia (Bering Strait to the Verkhoyansk Range), eastern Siberia (Verkhoyansk Range to the Yenisei valley), and western Siberia (Yenisei valley to the Urals). Although investigations into the late Pleistocene have occurred in many areas of northern Siberia, palynological research has focused on the following: (1) the northern Priokhot'ye, upper Kolyma drainage, and Yana-Indigirka-Kolyma lowland of northeast Siberia; (2) the Laptev Sea region of eastern Siberia; and (3) the Ob and Yenisei drainages of the Western Siberian Plain and the Jamal Peninsula of western Siberia.

The original late Pleistocene stratigraphy was proposed by [Saks \(1953\)](#) based on sections in western Siberia, and his scheme was subsequently applied throughout Siberia ([Table 1](#)). This stratigraphy included two cool or glacial intervals: the Sartanskaya and Zyrianskaya stades, which were later considered approximate equivalents to marine isotope stage (MIS) 2 and MIS 4, respectively. Two warm intervals were also defined: the Karginski interstade ($\sim$ MIS 3) and Kazantsevskoye interglaciation ($\sim$ MIS 5). The largest alteration of Saks' scheme was the elimination of the Zyrianskaya stage in western and eastern Siberia and its replacement by the Ermakovskaya stage, which encompasses MIS 4 and MIS 5a

through MIS 5d (see [Laukhin, 2011](#)). Continuing research has shown that key stratotypes used in defining the early stratigraphic schemes are no longer valid and questions persist concerning the timing and/or characteristics of the Siberian stratigraphy (see [Astakhov and Nazarov, 2010](#); [Laukhin, 2011](#) for western Siberia and [Sher et al., 2005](#) for eastern and northeastern Siberia). Despite proposed changes to the late Pleistocene nomenclature (e.g., [Astakhov and Nazarov, 2010](#)), the newest terminology has not as yet been recognized by the Russian International Stratigraphic Commission of the Quaternary. Thus, we will continue to refer to the four-part stratigraphy, which remains the interpretive framework in much of the Russian literature. Because of discrepancies in terminology and timing between the Siberian regions, we organize the chapter subheadings by isotope stages but with reference to the regional nomenclature. Although the late glaciation (~ 12500 – 10000 ^{14}C years BP) technically incorporates the latest Pleistocene, we do not include it here because postglacial warming throughout much of northern Siberia began ~ 12500 BP. The Zyrianskaya or late Ermakovskaya stage also is not discussed, because the vegetation throughout much of northern Siberia is inferred to be the same as in the better-studied Sartanskaya stade ([Figure 2](#)). We begin with the most recent cool interval, working back through time to the last interglaciation.

MIS 2 (Sartanskaya Stade)

Northern Asia experienced an incredible change in its geography during the Last Glacial Maximum (LGM; MIS 2). With lowered global sea levels, the continent was connected to North America via the Bering Land Bridge, and Siberia extended 400–700 km farther north, connecting the arctic islands to the mainland. This glacial interval is known for its abundance of large mammal remains and a curious pollen assemblage. The juxtaposition of faunal and floral paleodata, particularly in Beringia (from the Lena River to northwestern Canada) gave rise to a single question that has motivated research for decades: was the LGM vegetation a rich steppe that supported moderate to large populations of Pleistocene megafauna, or was it a depauperate tundra or polar desert where only a small number of these herd animals could survive?

The unusual pollen spectra that characterize the LGM records are dominated by graminoids (members of the grass (Poaceae) and sedge (Cyperaceae) families) and wormwood (*Artemisia*; MIS 2 zones in [Figures 3–6](#)). This assemblage has been reported in sites from the western Siberian Plain (see [Volkova, 2002](#)), Taymyr Peninsula (see [Andreev et al., 2011](#)), Laptev coast (see [Andreev et al., 2011](#)), Lena delta (see [Andreev et al., 2011](#); [Sher et al., 2005](#)), middle Lena drainage ([Müller et al., 2010](#)), New Siberian Islands (see [Andreev et al., 2011](#)), Yana-Indigirka-Kolyma lowlands (see [Lozhkin et al., 2002a](#)),

Figure 1 Map of northern Siberia showing locations named in the text. The site key is as follows: (1) Lake El'gygytyn; (2) Main river sites; (3) Duvanny Yar; (4) Lake Elikhan; (5) Lake Alut; (6) Kirgylakh mammoth site; (7) Lake Billyakh; (8) Oyogos Yar; (9) Bol'shoy Lyakhovsky Island; (10) Lena Delta sites, Mamontovy Khayata; (11) Yamal Peninsula sites; Lake Levinson-Lessing; (12) Yamal section sites; (13) Suryshkary and Zolotoy Mys sections.

Table 1 Late Pleistocene stratigraphic nomenclature, ages, and approximate marine isotope stage equivalents

Original Siberian scheme	Western Siberia	Eastern Siberia	Northeast Siberia
Sartanskaya MIS 2	Sartanskaya ~10 000–22/23 000 MIS 2	Sartanskaya ~10 300–30 000 MIS 2	Sartanskaya 12 500–26 500 MIS 2
Karginski MIS 3	Karginski ~22/23 000–50 000 MIS 3	Karginski ~30 000–50 000 MIS 3	Karginski ~26 500–60 000 MIS 3

upper Kolyma and upper Indigirka drainages (see Lozhkin et al., 2002a,b), northern Priokhot'ye (see Lozhkin et al., 2002a), and Chukotka (see Anderson et al., 2002a). Soviet scientists were the first to classify the glacial vegetation as tundra–steppe, suggesting that vast, relatively homogeneous and productive grassland covered northern Eurasia and far northwestern North America (see Yurtsev, 1982). This vegetation was also termed steppe–tundra and arctic steppe.

The LGM pollen spectra typically are associated with a faunal assemblage that is best known for the woolly mammoth (*Mammuthus primigenius*) and other large mammals, such as horse (*Equus*) and bison (*Bison*). The combination of faunal and paleobotanical data eventually gave rise to the concept of mammoth–steppe biome (see Guthrie, 1982). In the early 1980s, paleoecologists working with samples from lakes rather than sections noted that extremely low pollen accumulation

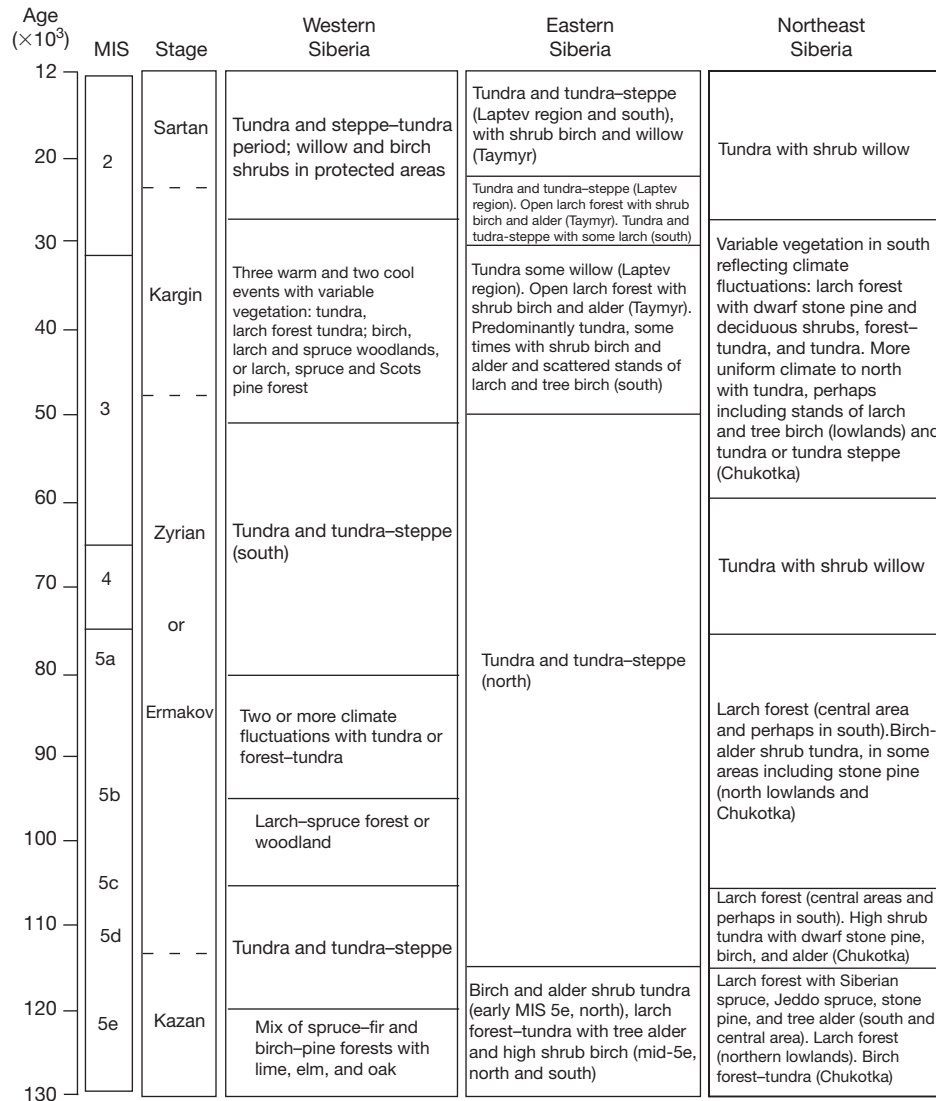

Figure 2 Vegetation of western, eastern, and northeast Siberia during the late Pleistocene. Age in the figure is in years before present $\times 10^3$.

rates and increased sedimentation in lake basins suggested unproductive landscapes, such as polar desert (see Hopkins et al., 1982). Furthermore, minor pollen taxa indicated comparatively depauperate arctic tundra rather than northern grassland. These conflicting interpretations gave rise to the 'productivity paradox': how could the late Pleistocene megafauna, which required seasonally rich vegetation growing in relatively fertile soils, survive in landscapes that were either barren or provided only limited food sources? Each side of this controversy found 'fatal flaws' in the other's data. For example, the vertebrate paleontologists noted that the major pollen taxa and many minor types represented ecologically diverse families or genera, making precise assignment to steppe or tundra impossible. The palynologists commented that poorly understood taphonomy and dating of many fossil-bone horizons prevented reasonable estimates of animal numbers or unquestionable co-occurrence of species at a site.

During the height of the productivity debate, a third line of thought developed that suggested neither extreme view was

correct. This thinking was led by Yurtsev (1982), who after further study of relict steppic communities found today in northeast and eastern Siberia, proposed that the LGM vegetation was more likely a tundra-steppe mosaic rather than a relatively uniform biome. He suggested that plant communities varied in composition and distribution based primarily on soil moisture and temperature. The most arid communities in this gradient experienced the greatest growing season warmth (thereby providing the most extensive summer thaw and soil aeration) and were most similar but not identical to zonal dry steppe. Plant associations more like those in arctic tundra occupied the other end of the gradient, occupying cool, poorly drained soils. Various grass-dominated communities (e.g., dry steppe-like meadows, mesic meadows) occurred between these extremes. Other paleoecologists, based on palynological data and/or feeding habits of the fauna, also proposed a landscape characterized by a mosaic of vegetation types (see Hopkins et al., 1982).

As further debate reached an impasse, scientists began pursuing other approaches for reconstructing the Sartanski

Figure 3 Pollen percentage diagram from Lake Levinson-Lessing, eastern Siberia. Data provided by A.A. Andreev (see Andreev et al., 2011). Figure shows pollen zones associated with the Holocene (HOL), late glaciation (LG), marine isotope stage 2 (MIS 2), and marine isotope stage 3 (MIS 3). High pollen percentages of shrubs (*B. sect. Nanae*, *Alnus fruticosa*) indicate shrub tundra and warmer conditions. High pollen percentages of *Cyperaceae* (sedge) and *Poaceae* (grass) indicate herb-dominated tundra or steppe-tundra and cool climate.

landscapes. Palynologists began looking for more rigorous methods that would improve upon the previous qualitative paleovegetation interpretations. For example, the collection of modern pollen samples from lakes and bogs throughout the arctic and subarctic greatly increased the ability to statistically define possible modern analogs for the MIS 2 vegetation. Comparisons using dissimilarity measurements have been done for high-latitude lakes in North America, but analogs have been calculated for only a single northern Siberian site (Lozhkin et al., 2007). Rather than indicating a no-analog landscape, as is often assumed for LGM spectra, statistics indicated that possible LGM analogs for Sartanski-age samples existed on southern and central Wrangel Island. Today, the vegetation on Wrangel Island is classified as discontinuous, herb-dominated arctic tundra, although Yurtsev (1982) noted that steppic plants are important components of some of the island's plant communities. He further suggested that these landscapes "may be the closest living approximations of the northern variants of late Pleistocene tundra-steppe" (Yurtsev, 1982, p. 172).

The development of computer models that merge an understanding of modern composition, structure, and function of arctic ecosystems with pollen-based vegetation reconstructions provide a second means for looking at LGM landscapes. These biome models use pollen data from a given time to assign plant functional types (e.g., tree vs. shrub, deciduous vs. evergreen). These types are then combined to determine a biome, the latter

being floristically distinguishable by plant and pollen composition and occupying a unique bioclimatic space (Kaplan et al., 2003). LGM biomes have been mapped for Beringia (Bigelow et al., 2003), the former Soviet Union (Tarasov et al., 2000), and the circum-arctic (Kaplan et al., 2003). Each of these experiments, including one in which the vegetation was determined using four different climate models (Kaplan et al., 2003), indicates an absence of forest and presence of various tundra types during the LGM. The mosaic nature of that tundra, including some communities with shrubby species, is particularly clear in Beringia (Bigelow et al., 2003). The indication from these analyses is that the vegetation of northern Siberia was more similar to tundra than steppe and that modern zonal steppe is not a regional analog for the Sartanskaya vegetation. In contrast, LGM biome reconstructions for Lake Billyakh (site 7, Figure 1) suggest a significant presence of both steppe and tundra communities in the southwestern foothills of the Verkhoyansk Range (Müller et al., 2010).

Another approach returned to the interdisciplinary investigations that characterized early Soviet research, with teams of Quaternary specialists gathering a broad spectrum of data (e.g., insects, plant and animal macrofossils, ostracods, cryolithology) to be used in paleoenvironmental reconstructions. Much of this research centered on the Laptev Sea region (see Andreev et al., 2011), with the Mamontovy Khayata site (site 10, Figure 1) being one of the most intensely studied (see Kienast et al.,

Figure 4 Summary pollen percentage diagram from Mamontovy Khayata, eastern Siberia. Data provided by A.A. Andreev (see [Andreev et al., 2011](#)). Zones correspond to marine isotope stages 1–4. High pollen percentages of grass (Poaceae) and sedge (Cyperaceae) indicate tundra or tundra steppe and cold climate. High percentages of shrubs (*B. sect. Nanae*, *Alnus fruticosa*) indicate shrub tundra and warmer conditions.

Figure 5 Pollen percentage diagram from Lake Elikchan, northeast Siberia. Modified with permission from Lozhkin and Anderson (2011) Forest or no forest: Implications of the vegetation record for climatic stability in Western Beringia during Oxygen Isotope Stage 3. *Quaternary Science Reviews* 30: 2160–2181. Figure 5(a) shows pollen zones associated with the Holocene (HOL), late glaciation (LG), marine isotope stage 2 (MIS 2), marine isotope stage 3 (MIS 3), and marine isotope stage 4 (MIS 4). Figure 5(b) illustrates fluctuations in pollen during MIS 3. Peaks in tree and shrub pollen reflect forest establishment, whereas high percentages of herb pollen indicate tundra.

Figure 6 Pollen percentage diagram from Lake El'gygytyn, northeast Siberia. Modified with permission from Lozhkin and Anderson (2011) Forest or no forest: Implications of the vegetation record for climatic stability in Western Beringia during Oxygen Isotope Stage 3. *Quaternary Science Reviews* 30: 2160–2181. Pollen zones in Figure 6(a) have been classified as Holocene (HOL), late glaciation (LG), and marine isotope stages 2–8. Figure 6(b) shows MIS 3–MIS 6 in more detail. Herb pollen is low during warm intervals and high during cold intervals. Highest percentages of shrub pollen indicate the warmest climate.

2005; Sher et al., 2005). Pollen data from this region are typically dominated by graminoids (Figure 4; zones III and IV), with minor pollen taxa suggesting variations in microhabitats. Plant macrofossil and insect data reveal a mosaic of arctic meadow and steppe communities, with habitats varying from extremely dry to aquatic. Kienast et al. (2005) noted many similarities to relict steppes of present-day eastern Siberia. The great taxonomic diversity at Mamontovy Khayata contrasts to the floristically depauperate polar desert, suggesting high arctic vegetation is an unlikely analog for the Sartanskaya stade (Sher et al., 2005).

In yet another approach, Andreev et al. (2011) noted variations in percentages of key pollen taxa in the Laptev Sea region. Particularly, wormwood pollen, an indicator of xeric and/or disturbed habitats, increases from east to west, suggesting more arid conditions in Taymyr Peninsula as compared, for example, to Bykovsky Peninsula (Figures 3 and 4). The Taymyr plant macrofossil data, with the predominance of xerophytic species, and the more mixed-habitat plant remains from the Bykovsky sites also support this conclusion (Kienast et al., 2001, 2005). Extending this comparison eastward, pollen data from northern Chukotka (e.g., site 1, Figures 1 and 6), and southern northeast Siberia (e.g., Elikchan (site 4, Figures 1 and 5)) show wormwood pollen that generally varies between ~10% and 20%. These values are greater as compared to Bykovsky Peninsula sites (typically <10%; e.g., site 10, Figures 1 and 4) but less than on Taymyr Peninsula (≥20%; e.g., Levinson-Lessing Lake, site 11, Figures 1 and 3), suggesting that the moistest areas in the far north occurred in eastern areas of the Laptev region. However, reliance on a single pollen taxon to infer dryness can be oversimplified. For example, Kuzmina et al. (2011), working in the Main River region (site 2, Figure 1), noted that the insect assemblage, which has few thermophilous steppe species, indicates relatively moist conditions in southern Chukotka, in contrast to other areas of northern Siberia. These results support previous conclusions that central Beringia was characterized by relatively mesic environments, which possibly acted as a 'barrier' preventing the dispersal of more xeric species between the two continents (see Elias and Crocker, 2008).

In addition to the proposed east-west gradients, a third spatial pattern involving tree presence is hinted at in the paleobotanical records. Tree pollen is rare in northern Siberian records. However, the low but consistent appearance of larch (*Larix*) pollen in the Billyakh Lake diagram indicates the local establishment of the tree (Müller et al., 2010). As suggested by the biome reconstructions, tundra-steppe or tundra was the dominant vegetation, but stands of Dahurian larch (*Larix dahurica*) likely were distributed in protected valley sites, possibly throughout southeastern areas of eastern Siberia. Pollen data from western Siberia indicate forest-tundra, formed by Siberian spruce (*Picea obovata*) and Siberian larch (*Larix sibirica*) established in areas to the south of 56° N (see Volkova, 2002). These data suggest a zonal distribution of tundra/tundra-steppe to the north and forest-tundra to the south during the LGM. However, plant macrofossil studies indicate that larch and spruce were present at least in small populations on southern Taymyr Peninsula ~18 000–19 000 years ago (Binney et al., 2009), raising the possible existence of refugial forest communities in the far north. These cryptic refugia in the Siberian lowlands possibly acted as seed sources for the repopulation of larch which established in the northern interior during the Holocene (Anderson et al., 2002b).

The above approaches bring much needed new information and analyses to the 'productivity' debate, even though they resolve the past environments on differing spatial scales. That is, models relying on palynological data emphasize broad vegetation types, whereas multidisciplinary studies provide insights into relatively local landscapes. Nonetheless, points of agreement do exist. The Sartanskaya vegetation was a mosaic of herb-dominated communities that contained elements of arctic tundra and steppe. In the most severe areas, vegetation was likely discontinuous. Shrubs, particularly willow (*Salix*) and birch (*Betula* sect. *Nanae*), were present but restricted to more mesic and protected sites. Small populations of larch may have survived the LGM in southern areas of northern Siberia or in cryptic refugia in the northern lowlands. The mosaic quality of the vegetation was apparently independent of topography, because it characterized both the Siberian lowlands and more mountainous areas to the south. As Schweger et al. (1982) noted, the survival of the late Pleistocene megafauna was perhaps more dependent on a mosaic of grazing habitats rather than the occurrence of a single, highly productive, uniform habitat.

MIS 3 (Karginski Interstade)

Although the Karginski interstade was defined by Saks in the 1950s, it was only some 20 years later that Kind (1974) formalized the sequences of interstadial climatic changes into three warm and two cool events (Table 2). While many

Table 2 Examples of Karginski interstadial divisions

Age (years BP × 10 ³)	Subhorizon name	Relative climate within Karginski interstade

Siberian paleoecologists accepted this stratigraphic framework, others have long doubted its validity. V.I. Astakov and A.V. Sher were two of the most vocal opponents, with arguments centering on the following: (1) the accuracy of age assignments of the Karginski deposits and (2) whether interstadial environments were significantly warmer than during MIS 2. Astakov and colleagues returned to key western Siberian sections to redate the basic sediment stratigraphy, using ^{14}C , luminescence, and Th/U techniques (see Astakhov and Nazarov, 2010). They found that the original stratotype for the Karginski interstade was invalid, because the 'interstadial' units actually dated to $\sim 130\,000$ years ago (i.e., MIS 5e). This finding supported conclusions drawn by Sher and colleagues, who, based on paleoecological data from well-dated sites in the northern lowlands, inferred that conditions varied little between MIS2 and MIS3, with sites previously assigned to the Karginskaya stage being more likely of last interglacial age (see Sher et al., 2005). Additional investigations into the timing and nature of the late Pleistocene in western Siberia, headed by Laukhin (2011), agreed that the original Karginski stratotype was invalid, but other dated sections indicated Kind's scheme to be basically accurate. Lozhkin and Anderson (2011) in a summary of MIS 3 pollen data from western Beringia proposed that aspects of both Kind's and Sher's arguments were correct with interstadial variability characterizing southern areas and with more stable, stadial-like environments in the north. As suggested by these discussions and outlined in the following vegetation history (Figure 2), the Karginski interstade appears to be distinguished by complex spatial and temporal patterns that set it apart from stadial environments.

From the earliest studies, palynological research in northeast Siberia documented spatial and temporal variability in MIS 3 vegetation and climate (see Anderson and Lozhkin, 2001). Although the age assignments of some sites to the Karginski interstade have been questioned (see Sher et al., 2005), the Elikchan (site 4 Figures 1 and 5) and Alut (site 5, Figure 1) lake records confirm the instability of interstadial vegetation with forests likely expanding and contracting rather rapidly, at least in southwestern areas of the region (Lozhkin and Anderson, 2011). The Elikchan record suggests that MIS 3 experienced two warm (zones EL2a–EL2c; EL2g–EL2i), two cool (EL2d, EL2f), and two moderate (EL2e, EL2j) intervals with vegetation shifting from near modern (i.e., Dahurian larch with dwarf stone pine, *Pinus pumila*) to shrub tundra. The timing of the paleoclimatic changes is still problematic (Lozhkin and Anderson, 2011) with contradictions occurring between lakes and with some of the better-dated sections. For example, the Kirgilyakhski interval, defined from the Kirgilyakh mammoth site (site 6, Figure 1), indicates cool conditions from $\sim 40\,000$ to $44\,000$ BP (Anderson and Lozhkin, 2001). Such an interpretation is in agreement with the Alut record but corresponds to a warm interval at Elikchan Lake. The southern lake and section data do concur that the interstadial climatic optimum happened in mid-Karginski times, as was suggested by Kind (Table 2). During this interval, vegetation and climate are inferred to be like modern (cf. zone EL2g, Figure 5(b) to zone HOL, Figure 5(a)).

In Chukotka, El'gygytyn Lake (site 1, Figures 1 and 6) provides the most continuous vegetation history for MIS 3, although the level of analysis is not comparable to that from the southern lakes (Lozhkin and Anderson, 2011).

Shrub tundra persisted in the El'gygytyn region throughout the interstade. However, relatively high percentages of alder (*Alnus*) pollen suggest that summers were somewhat warmer $\sim 54\,000$ – $60\,000$ BP (zone EG10a, Figure 6(b)) as compared to $\sim 46\,000$ – $27\,000$ BP (zone EG10c). A similar shift from relatively warm to cooler conditions is recorded in several Main River sites in southern Chukotka (site 2, Figure 1), with indications of scattered larch stands during warmer intervals (Anderson et al., 2002a). The northern establishment of Dahurian larch–birch woodlands or forest–tundra in the Yana–Indigirka–Kolyma lowlands was inferred from pollen data (Anderson and Lozhkin, 2001), although site assignment to the Karginski interval subsequently was questioned (see Sher et al., 2005). However, the recent discovery of larch trunks in a peat horizon dated to $\sim 40\,000$ – $43\,000$ BP at the Duvanny Yar site (site 3, Figure 1; Zanina et al., 2011) suggests that the initial age assignments and paleovegetation interpretations are correct. Additional paleobotanical data from Duvanny Yar support the presence of open Dahurian larch forest with alder, birch, and willow shrubs, implying a climate similar to modern at this time. Between $\sim 35\,000$ and $38\,000$ BP, moist tundra was dominant in the lowlands, suggesting cooler and/or drier conditions.

Eastern portions of the eastern Siberia lowlands were dominated by treeless vegetation during MIS 3 (see Andreev et al., 2011; Figure 4), although low percentages (2–9%) of forest–tundra insects indicate the existence of small pockets of Dahurian larch (Sher et al., 2005). Numerous ^{14}C -dated sites record the dominance of tundra–steppe or tundra with a mosaic of graminoid meadows, steppic and disturbed habitats, and willow thickets in protected settings. The monolithic nature of the MIS 3 and MIS 2 environments, particularly as documented from Bykovsky Peninsula (site 10, Figure 1), confirmed to Sher and colleagues that interstadial conditions were essentially stable across northern Siberia and that the environmental fluctuations proposed by Kind were in error (Sher et al., 2005). However, they also noted that several bioindicators suggested somewhat warmer summer climates between $32\,000$ and $42\,000$ BP, giving some small degree of variability to the interstade (Andreev et al., 2011; Kienast et al., 2005; Sher et al., 2005).

In contrast to the Lena delta region, open Dahurian larch forests with shrub birch and alder established in the Taymyr lowland (site 11, Figures 1 and 3) from $\sim 48\,000$ to $25\,000$ BP, suggesting a climate that was warmer and wetter than modern (see Andreev et al., 2011). However, discontinuous steppic vegetation characterized northern areas of the Peninsula from $\sim 32\,000$ BP throughout MIS 2. Herb-dominated communities also prevailed during the interstade in southeastern eastern Siberia. The Lake Billyakh record (site 7; Figure 1) suggests modest climatic differentiation, as increases in Dahurian larch and shrub birch hint at somewhat ameliorated conditions prior to $\sim 31\,000$ BP (Müller et al., 2010). Evidence for sustained warm periods is absent, although brief and relatively warm events occurred $\sim 47\,500$, $\sim 38\,000$, and $\sim 33\,000$ BP.

Despite reassigning the original Karginski stratotype to MIS 5e, additional research in the Western Siberian Plain suggests much of the original paleoenvironmental history is valid (see Arkhipov and Volkova, 1994). For example, the Shuryshkary sections (site 13; Figure 1) contain 'warm' deposits occurring stratigraphically between stadial sediments and above a last

interglacial horizon (see [Laukhin, 2011](#)). Paleobotanical data revealed variable interstadial conditions as represented by fluctuating vegetation types: (1) forest–tundra; (2) north taiga open woodland (tree birch (*Betula* sect. *Albae*), Siberian spruce, Scots pine (*Pinus sylvestris*), and Siberian stone pine (*Pinus sibirica*)); (3) southern north taiga; (4) south taiga (climatic optimum; Scots pine, Siberian spruce, Siberian fir (*Abies sibirica*), tree birch); (5) dark coniferous woodland; (6) forest–tundra; (7) tundra; and (8) forest–tundra ([Volkova et al., 2003](#)). This scheme is more complex than Kind’s original stratigraphy and is more in line with the numerous vegetation fluctuations in southern northeast Siberia. In contrast, data from Yamal Peninsula (site 12, [Figure 1](#)) record relatively stable climate as indicated by persistent graminoid tundra between ~33 000 and 25 000 BP ([Andreev et al., 2006](#)). This stable pattern has a greater affinity to northern eastern Siberia.

MIS 5 (Mid- and Lower Ermakovski and Kazantsevskoye Stages, Western and Eastern Siberia; Kazantsevskoye Stage, Northeast Siberia)

As compared to other late Pleistocene stages, little controversy exists concerning the paleoenvironments of the last interglaciation. Although stratigraphic issues are not completely

resolved (e.g., [Astakhov and Nazarov, 2010](#); [Laukhin, 2011](#)), there is a general consensus that modern vegetation zones moved hundreds of km northward ([Figure 2](#)) and that climate was significantly warmer than the present during the climatic optimum.

Most of northeast Siberia was dominated by forest during MIS 5e ([Lozhkin and Anderson, 1995](#)). As compared to the modern vegetation, the interglacial forests of the Magadan region contained greater numbers of tree birch and temperate trees (Jeddo spruce (*Picea ajanensis*), fir (*Abies*), hazel (*Corylus*), tree alder), representing range extensions of up to 1000 km. Like today, the interior supported Dahurian larch forest, but this forest included Siberian spruce and tree alder (*Alnus hirsuta*). The presence of Siberian spruce in the upper Kolyma and Indigirka drainages suggest range extensions of ~700–800 km. Dahurian larch migrated ~600 km northward, eliminating coastal tundra and a similar distance eastward into areas of southern Chukotka. Birch forests also established in parts of Chukotka, representing northward range extensions of ~1000 (*Betula ermanii*) and ~600 km (*Betula cajanderi*). El’gygytyn Lake (site 1, [Figure 1](#)) is the only continuous record of paleoenvironmental change for all of northern Siberia ([Lozhkin et al., 2007](#)) and provides some of the best documentation of vegetation and climate change within MIS 5. For example, El’gygytyn pollen data indicate an increase in dwarf stone

Figure 7 Summary pollen percentage diagram from Oyogos Yar, eastern Siberia, showing the climatic optimum of the last interglaciation (marine isotope stage 5e). Data provided by A.A. Andreev (see [Andreev et al., 2011](#)). The high percentages of larch (*Larix*), which is an underrepresented pollen type, suggest the establishment of larch forest or forest–tundra and warmer than present climate.

pine during MIS 5d (Figure 6; zone EG 7), suggesting greater winter precipitation as compared to the climatic optimum (zone EG 6). Substages 5a–5c (zone EG 8) are indistinguishable, but plant communities and thus climate appear similar to modern.

In eastern Siberia, shrub tundra with shrub birch and alder established on Bol'shoy Lyakhovsky Island (site 9, Figure 1) during the early and middle portions of the climatic optimum (see Andreev et al., 2011). Plant macrofossils for this interval consisted mainly of subarctic shrub taxa (Kienast et al., 2008). At the same time, paleobotanical and insect data indicate the presence of larch forest or forest–tundra with shrub alder and birch, representing a ~270-km northward displacement (see Andreev et al., 2011). Pollen data from the Oyogos Yar site (site 8, Figures 1 and 7) confirm the presence of larch during MIS 5e. Scattered stands of tree birch may also have been present. Additionally, forests established in the western Laptev Sea region and in the middle Lena drainage (Andreev et al., 2011).

Although Astakhov and Nazarov (2010) suggested that most western Siberian sites previously assigned to the Kazantsevskoye interglaciation are more likely of middle Pleistocene age, recent studies have confirmed the occurrence of interglacial sites in the region (Laukhin, 2011; e.g., Shuryshkary section, lower Zolotoy Mys, site 13, Figure 1). In the western Siberian Plain, MIS 5e is marked by the northward displacement of all vegetation zones by as much as 700 km (Arkipov and Volkova, 1994; Volkova et al., 2003; Figure 2). Dark coniferous forest (e.g., Siberian spruce, Siberian fir, Siberian stone pine) occupied the northern plain, extending to the current coastline and eliminating arctic tundra and forest–tundra landscapes. Southern areas of this conifer-dominated taiga included broadleaf species (e.g., linden (*Tilia*), elm (*Ulmus*), oak (*Quercus*), hazel). Today, oak and hazel are not found east of the Urals, indicating a ~2000-km range extension (Volkova et al., 2003). Some variability may have occurred during MIS 5e (Laukhin, 2011), but additional data are required to confirm these trends. MIS 5d is marked by a dramatic vegetation change to tundra or tundra–steppe, whereas MIS 5c is characterized by Siberian larch–Siberian spruce forest or open woodland. The latest vegetation of late MIS 5 was birch forest–tundra.

Introduction

This entry summarizes our current knowledge of late Quaternary pollen-based vegetation reconstructions in northern North America, north of about 60°N.

The vegetation of northern North America is primarily boreal forest and tundra. In most areas, the boreal forest is dominated by conifers (depending on locality, spruce, pine, larch, or toward the south, fir), although in some areas, birch or aspen may be important (Elliott-Fisk, 2000). The tundra vegetation varies depending on climate and substrate. Graminoid meadows or tussock tundra are common on water-saturated landscapes, while shrubs are found in better-drained settings. Shrubs become progressively shorter and less frequent toward the north. In the northernmost Arctic, shrubs are excluded entirely, and the vegetation is a sparse covering of grasses, mosses, lichens, and liverworts (CAVM Team, 2003).

Regionally, the northern limit of trees is controlled by climate, but on a local scale, factors such as aspect and drainage exert a strong influence. Spruce and pine are the dominant treeline species across the continent, though stands of cottonwood north of the treeline are present in Alaska (Viereck and Little, 1975). Treeline in central Canada is a gradational boundary, with a wide swath of lichen woodland and forest-tundra separating the closed forest from the tundra (Figure 1) (Elliott-Fisk, 2000).

This article covers the time period from the last interglaciation (ca. 125 ka) to the late Holocene. All ages are written in kiloyears and abbreviated as 'ka' (thousands of years ago). All radiocarbon dates younger than about 21 ¹⁴C ka have been calibrated by Calib ver. 5.0.1 (Stuiver and Reimer, 1993) and are written as 'ka.' Ages from other dating methods (e.g., luminescence) are assumed to correlate with the calibrated radiocarbon timescale and are also written as 'ka.'

Summary of Pollen Records in Northern North America

Alaska and Yukon

Marine Isotope Stage 5 (MIS 5 (ca. 128–73 ka)) is a complex period of warm (MIS 5e, 5c, 5a) and cool (5d and 5b) episodes. The entire interval is colloquially known as the last interglaciation, although in the Arctic, probably only the climate at onset (MIS 5e) was similar or warmer than today (CAPE Last Interglacial Project Members, 2006). MIS 5-aged sites are primarily located in areas that were unglaciated during the last Ice Age (MIS 2), such as the northern half of Alaska, the northern Yukon, and unglaciated uplands of Baffin Island (Figure 1). In western Alaska, lake cores (e.g., Squirrel Lake (Figure 2)) and peat deposits (Edwards et al., 2003; Matthews, 1974a) indicate the westward and northward expansion of

spruce. Buried near-shore marine deposits on Togiak Bay (Figure 2) in southwest Alaska (CAPE Last Interglacial Project Members, 2006; Kaufman et al., 2001) also probably document spruce expansion. Spruce distribution in the north is a function of summer climate, indicating that in the north and west, at least, summers were warmer than they are today. In interior Alaska, pollen records from several sites are not significantly different from today's, except that ferns (Polypodiaceae) were apparently more abundant, suggesting wetter and possibly warmer climate than today (CAPE Last Interglacial Project Members, 2006). Near treeline in the northern Yukon today, pollen analyses of MIS 5-aged peat at Ch'ijee's Bluff indicate northward expansion of spruce and *Typha* (cattail) (Figure 2). Many of the peat sites mentioned above also have detailed plant macrofossil records, which provide additional strong evidence for the local presence of spruce and other taxa far north of their current limits. MIS 5-aged pollen has also been recovered from Baffin Island; see 'Canada East of the Yukon' below.

Pollen records dating to MIS 4 (ca. 72–60 ka) and MIS 3 (ca. 60–30 ka) indicate widespread tundra across Alaska, although some spruce were present in the Alaskan interior, the Yukon, and probably on the Bering Land Bridge during MIS 3 (Matthews, 1974b; Wooller et al., 2011; Wetterich et al., 2012). In western Alaska, the record from Squirrel Lake is dominated by grass, sedge, and *Artemisia* pollen with minor amounts of willow and birch (Anderson and Lozhkin, 2001), although a pollen study from the western Seward Peninsula consistently records about 20% spruce during MIS 3, indicating the trees were present, probably on the land bridge itself (Wetterich et al., 2012). Sites in the Yukon are all terrestrial peat deposits; at most localities, spruce pollen frequencies are less than 20%, suggesting only scattered trees within a birch or graminoid tundra (Schweger and Matthews, 1991). However, abundant spruce needles and pollen were recovered in sediments dated to about 38 ka, indicating that spruce may have been locally abundant (Matthews et al., 1990a).

The most recent glaciation (MIS 2 (ca. 29–18 ka)) was a period of severe climate, with maximum cooling during the Last Glacial Maximum (LGM) about 21 ka. Pollen records from unglaciated Alaska and the Yukon (Figure 3) indicate the vegetation was herb and forb dominated, with grass, sedge, and *Artemisia* being the most common taxa. As a rule, sites in western Alaska (i.e., Zagoskin, Kaiyak, and Burial lakes) contain more *Thalictrum* (tundra and woodland plant that favors wet meadows and bogs) than sites to the east (i.e., Bluefish Exposure) (Abbott et al., 2010; Ager, 2003; Anderson, 1985; Zazula et al., 2006a). In addition, the well-preserved Kitluk soil on the Seward Peninsula (Goetcheus and Birks, 2001; Wolf, 2001) and some peat cores from the Bering Land Bridge (Elias et al., 1996) (Figure 1) contain higher frequencies of shrub pollen than sites further inland. Taken together, these data suggest a moisture gradient (as there is today) from a

Figure 1 Map showing localities that are mentioned in the text. Alaskan treeline is based on *Alaska Trees and Shrubs* (Viereck and Little, 1972) and the Canadian treeline is based on *The National Atlas of Canada*, 5th edn. (Energy Mines and Resources Canada, 1993).

relatively mesic west to a drier east. However, macrofossils from the Kitluk soil also indicate a dry-adapted vegetation on the uplands of the Seward Peninsula and a peat core from Norton Sound, just south of the Seward Peninsula (Ager and Phillips, 2008), contains little shrub pollen, suggesting the shrubs were patchy and the vegetation was a mosaic.

The Late Glacial (ca. 18–12 ka) marks the transition from full glacial conditions to the onset of postglacial warming. As climate warmed during this transition, effective moisture (precipitation minus evaporation) increased, so that many lakes came into existence, especially after about 16–14 ka. From the LGM to about 16 ka, pollen records remain dominantly unchanging (mostly graminoids and forbs), but after about 16 ka, birch pollen becomes significantly more important across the region ('the birch rise'), from western Alaska to the Mackenzie River (Figures 1 and 4) (Anderson et al., 2004; Ritchie, 1984). This change in the pollen records marks a significant shift in the vegetation from a dominantly herbaceous tundra to a dominantly shrub tundra, probably reflecting both increasing summer warmth and increased moisture (Finney et al., 2004). The apparent absence of a pattern in the birch expansion, along with its astonishingly rapid rise at some sites, suggests that it survived the LGM *in situ* in protected sites, perhaps reproducing vegetatively (Brubaker et al., 2005).

In the early Holocene (ca. 11–8 ka), many sites across interior Alaska and the Yukon (and western Northwest Territory) contain a short episode of elevated *Populus* (probably cottonwood (*Populus balsamifera*)) and *Salix* (willow) pollen frequencies. *Populus* pollen does not preserve well or travel far from its source (Edwards and Dunwiddie, 1985); frequencies preserved in the pollen records (up to 20%) are far higher than

modern frequencies, indicating widespread *Populus*, possibly as gallery forests along streams (Anderson et al., 2004). Due to a combination of bulk radiocarbon samples and changes in ^{14}C production in the atmosphere, precisely dating the *Populus* zone is problematic (Bartlein et al., 1995), but the period dates roughly between about 12 ka and 10 ka BP (Edwards et al., 2005). Significant *Populus/Salix* woodland development occurred in interior Alaska, the north slope of the Brooks Range (along with abundant cottonwood macrofossils (Mann et al., 2010)), interior Yukon, and western Northwest Territory (Anderson et al., 2004; Ritchie, 1987). *Populus* probably survived in the region during the LGM (Brubaker et al., 2005), although genetic analyses cannot yet identify the refugial population (Breen et al., 2012). Today, *P. balsamifera* forms clonal stands far north of the spruce limit, easily propagates vegetatively, and could have survived the LGM as isolated gallery stands in protected river floodplains.

Spruce pollen and macrofossils appeared in interior Alaska after the *Populus/Salix* expansion, suggesting it was growing locally at least by 10 ka and possibly slightly earlier (Figure 4). However, many pollen records contain low spruce frequencies (<5%) prior to the main spruce rise. This may suggest its survival as refugial populations during the LGM (Brubaker et al., 2005). While the northern limit of spruce in Alaska did not expand beyond its current limits during the early Holocene, a single spruce twig dated to about 9.2 ka was recently recovered from north-coastal Seward Peninsula (Figure 1) (Wetterich et al., 2012). Pollen morphological analyses elsewhere indicate the earliest Holocene-aged spruce pollen in Alaska and the Yukon was from white spruce, later shifting to black spruce about 5 ka (Anderson et al., 2004).

Figure 2 MIS 5-aged pollen records in Alaska and the Yukon. The data are redrawn from publications (Ch'ijee's Bluff (Matthews et al., 1990b) and Togiak Bay (Kaufman et al., 2001)) or kindly provided by the analyst (Squirrel Lake (P. Anderson)). In all records for this and other figures, terrestrial pollen percents are based on the sum of all terrestrial pollen, while spore percentages are based on the sum of terrestrial pollen and spores.

Figure 3 MIS 3 to MIS 2-aged pollen records in Alaska and the Yukon. The data are either redrawn from publications (Bluefish Exposure (Zazula et al., 2006a)) or are calculated from raw pollen data housed in the Neotoma Paleocology Database (see ‘Relevant Websites’ for the URL). Age models in this and subsequent figures are either the author’s published chronology, or in the case where calibrated time scales needed to be built, the dates thought accurate by the investigator with the calibrated age being the median of a one standard deviation probability curve for that date have been used (Reimer et al., 2004). The chronology was then modeled using linear interpolation between the calibrated dates.

Figure 4 Late Glacial and Holocene-aged pollen records from Alaska and the Yukon. All the pollen data are available at the Neotoma Paleocology Database. Age models are as in **Figure 3**.

By about 10 ka, the alder pollen frequency increased rapidly in northwestern and southwestern Alaskan pollen cores (Figure 4). In the Alaskan interior and Yukon, alder frequencies crossed the 20% threshold (indicating local presence) by about 7–8 ka, and slightly later immediately north of the Brooks Range (Anderson et al., 2004). The very rapid alder rise in the western cores, combined with an apparent delay to the east, suggests alder survived the LGM, either in Alaska or on the now-submerged Bering Land Bridge (Brubaker et al., 2005).

Because it was ice-covered during the last glaciation, southern Alaska has a different vegetation history than interior and northern Alaska. Deglaciation is dated to shortly before 14 ka around Cook Inlet (Figure 1) (Reger et al., 2007). Unlike sites in the interior, only a few records indicate a brief period of herbaceous tundra prior to the development of a birch-dominated tundra (Ager and Brubaker, 1985). Peat cores from the northern Kenai Peninsula (Figure 1) indicate the development of birch shrub tundra by about 14 ka (Jones et al., 2009). While just northeast of Anchorage (Figure 1), this transition is dated to about 13 ka (Yu et al., 2008). At roughly 9–11 ka, sites on the Anchorage Lowland and Kenai Peninsula record transient increases in *Populus* and willow frequencies (Ager and Brubaker, 1985; Anderson et al., 2006b; Jones et al., 2009) similar to that seen in the interior. Shortly afterward, alder frequencies increase, indicating a shift to an alder-dominated vegetation, at least in some sites (Ager, 1983; Ager and Brubaker, 1985; Anderson et al., 2006b; Jones et al., 2009). This alder rise is earlier on the Kenai Peninsula than in the interior (roughly 9–10 ka on the Kenai Peninsula vs. 7–8 ka in the interior), which is consistent with the early alder to the south. Spruce was probably locally present as early as 10 ka at Hidden Lake (Figure 4) and by about 5 ka in the southern Kenai Peninsula. Spruce pollen is not differentiated between interior and coastal species, but it may initially document the arrival of interior taxa, followed by the coastal Sitka spruce in the late Holocene (Ager, 2000). Lastly, mountain hemlock was present locally within the past few thousand years.

Some sites around the Gulf of Alaska clearly record a brief period (ca. 13–11 ka) of tundra expansion at the expense of boreal shrubs and trees. The timing of this shift suggests it is correlated with the well-known Younger Dryas event (Kokorowski et al., 2008). Pleasant Island in southeast Alaska documents the expansion of herbs at the expense of pine and alder, while a pollen and macrofossil record from southwestern Kodiak Island indicates the expansion of a heath vegetation and loss of ferns (Kokorowski et al., 2008). Hidden Lake (Figure 4) also documents a reduction of ferns but slightly earlier. Taken together, these records indicate a brief episode of cooler and/or drier climate. Although the evidence is most compelling at the Gulf of Alaska sites, there is some evidence that similar vegetation shifts are documented in southwest Alaska, in the Alaska Range, and north of the Brooks Range (Kokorowski et al., 2008).

Canada East of the Yukon

During MIS 5, several lakes on Baffin Island (Figure 1) document MIS 5 vegetation (Frechette et al., 2006; Miller et al., 1999). In all cases, the lakes record increased shrubs (birch, alder, and willow) and higher pollen concentration relative to

today. These and other proxies (Francis et al., 2006) suggest that summer air temperatures were significantly warmer than modern, which is consistent with the contemporaneous sites in the Yukon and Alaska.

The Laurentide and Innuitian ice sheets covered much of northern Canada during the last glaciation. However, northwestern Northwest Territories and some of the Arctic islands were unglaciated during MIS 2 (Dyke et al., 2002). Laurentide deglaciation began in the west, with the Mackenzie Delta and Tuktoyaktuk Peninsula (Figure 1) being deglaciated by about 14 ka, although the Hudson Bay basin was still ice-covered around 8.5 ka, and the last remnant of ice did not disappear from northern Québec until after about 6 ka (Dyke, 2004). The Innuitian ice sheet covered the Canadian Arctic Archipelago until about 10 ka (or perhaps earlier – see Dyke, 2004), with subsequent rapid retreat over the next millennium, so that by about 8.5 ka much of the ice sheet had reached its contemporary ice limits (England et al., 2006). As a result of this asymmetrical melting of the two ice sheets, much of the Arctic Archipelago was deglaciated several millennia before northern Québec and Labrador.

On the Tuktoyaktuk Peninsula (Sleet Lake, Figures 1 and 5), a birch shrub tundra from about 14 ka to about 12 ka is interrupted by the spread of spruce and a boreal shrub, sweet gale (*Myrica*), ca. 12–8 ka, indicating a 30–40 km extension of tree-line (spruce needles were also recovered), which retreated southward by about 8 ka (Spear, 1993). After 8 ka, the pollen record is dominated by birch and alder, indicating the establishment of the modern tundra at about this time. At a higher elevation on the Brock Plateau to the east (Figure 1), a pollen record beginning by about 13.9 ka (possibly as early as 16 ka) indicates the vegetation was initially an *Artemisia*-willow tundra, suggesting very dry conditions. A birch shrub tundra grew in the area by about 11 ka (with no evidence of a spruce expansion) and the regional expansion of alder occurred by about 7 ka, although it is unclear whether it grew locally or not (Ruhland et al., 2009).

Lakes in the Mackenzie drainage to the south (MacDonald, 1995) and in the Mackenzie Mountains to the west (i.e., Keele Lake (Szeicz and MacDonald, 2001); Figure 5) record the presence of a birch shrub tundra by about 13 ka. Spruce (initially white spruce, with black spruce shortly afterward) was probably locally present shortly before about 11 ka along the Mackenzie River but was later in the mountains (about 9 ka), probably due to cooler temperatures at higher elevations. Increased spruce pollen influx during the early to middle Holocene in the alpine sites also indicates that spruce may have been more abundant or treeline slightly higher than it is today.

So far, the oldest reliably dated postglacial pollen record from the Canadian Arctic Archipelago is from Melville Island (Figures 1 and 6), where the record begins about 13 ka, suggesting that deglaciation was earlier here than elsewhere. Here, the initial vegetation was grass-dominated, with sedges and *Oxyria digyna* (an Arctic/alpine snowbed plant) as secondary taxa (Peros et al., 2010). Other Arctic Archipelago pollen records (Banks, Victoria, and Ellesmere islands) begin about 10 or 11 ka (Figures 1 and 6), shortly after deglaciation (with the exception of Banks Island which was mostly unglaciated during MIS 2). Graminoids dominate all records at their outset, though *Artemisia* and willows are abundant initially on Victoria Island (Peros and Gajewski, 2008) and *Oxyria digyna* is common at

Figure 5 Late Glacial and Holocene-aged pollen records from Northwest Territories, Nunavut, Québec, and Labrador. All the data are available in the Neotoma Paleocology Database. The Sleet Lake chronology follows the depth-age model recommended by the analyst (Spear, 1993); other age models are as in Figure 3.

Figure 6 Holocene-aged pollen records from Arctic Canada. With the exception of Lake BC01 (Peros et al., 2010), all the data are available in the Neotoma Paleoecology Database and age models are as in Figure 3. Local/regional terrestrial pollen percentages are based on the sum of the local and regional terrestrial taxa. Long-distance percentages are based on the sum of the local/regional taxa plus the long-distance taxa. Note that *Betula* is considered local/regional in the southern to middle Arctic, while it is considered long-distance in the northern Arctic. In addition, the basal sample from Baird Inlet contains 53 long-distance pollen grains, but only six local pollen grains (four are Ericales). As a result, the local pollen frequencies are highly skewed and have been omitted from the diagram, even though the long-distance taxa are still shown.

Baird Inlet on Ellesmere Island (Hyvärinen, 1985). Willows are more abundant at several of these sites (i.e., Victoria, Melville, Somerset, and Ellesmere islands) during the early Holocene than they are today (Figure 6). In addition, pollen concentrations (and influx when it is calculated) are often higher during the early Holocene than today, suggesting that plant abundance and productivity was greater than today.

On Baffin Island (Figures 1 and 6), despite some local variation, grasses and/or sedges dominate the early Holocene vegetation. In the south, some shrubs (heaths) were present, while in the north, forbs and, in one case, ferns were relatively important (Gajewski and MacDonald, 2004; Short et al., 1985). Off the southern tip of Baffin Island, the Robinson Lake pollen record is initially dominated by grass, followed by a transition to sedge and *O. digyna*-dominated tundra (Miller et al., 1999).

By the middle Holocene (ca. 7 ka), Canada was mostly deglaciated. Lakes that were already in existence prior to this time generally document the development of the modern vegetation by about 7 ka. However, several records also document vegetation succession following deglaciation, while others suggest mid-Holocene treeline fluctuations.

Several pollen cores (cf. Queen's Lake (Figure 5)) from the forest-tundra ecotone indicate that a birch shrub tundra was well established before ca. 8 ka and alder became important by about 7 ka. Spruce (probably black spruce) pollen frequencies reached maximum amounts (up to 40%) about 7–4.5 ka, decreasing gradually afterward, indicating a treeline advance that is asynchronous with the early Holocene treeline changes documented on the Tuktoyaktuk Peninsula. Pine (*Pinus*) pollen frequencies increase to modern levels by about 2 ka, probably reflecting population growth south of the site (Gajewski and MacDonald, 2004).

A transect of pollen records crossing the treeline of interior Québec indicates that shortly after deglaciation (ca. 7 ka), alder and spruce (probably black spruce) pollen frequencies rapidly increased, reaching their northern limits by about 6 ka. In addition, one site also suggests the expansion of cottonwood (*Populus*) and larch (*Larix*), indicating that the earliest forest was somewhat different from today's (Gajewski and MacDonald, 2004). Alder frequencies are at their highest in the middle Holocene, decreasing about 4.5 ka. For the past 3 ka, within the forest-tundra, spruce pollen frequencies decreased gradually, while birch and nonarboreal pollen increased, suggesting slow deforestation (Gajewski and MacDonald, 2004), although the overall forest limit in this region is notable for its apparent stability throughout the middle and late Holocene (Payette et al., 2002).

Coastal regions of northern Québec were probably ice-free by about 8 ka (Dyke, 2004). The pollen record from Diana-375 (Figure 5) documents an initial postglacial vegetation of herbaceous tundra, which was replaced by a birch and alder shrub tundra by about 6.8 ka. Shrub pollen frequencies decrease by about 3.7 ka, concurrent with increases in graminoid pollen, suggesting an expansion of herbaceous (sedge-dominated) tundra in the late Holocene (Richard, 1981).

In northern Labrador, like Québec, pollen records document the rapid colonization of the landscape after deglaciation. Coastal regions may have been ice-free as early as 9 ka, while the interior was still ice-covered until about 8 ka (Dyke, 2004). Despite a basal date that is possibly too old

(ca. 12 ka), the coastal site of Ubluk Pond (Figure 5) (Short and Nichols, 1977) documents a brief period of graminoid and willow tundra preceding the transition to a birch shrub tundra, which was followed by alder expansion about 7.5 ka. Spruce frequencies begin increasing about 5 ka, reaching maximum amounts (ca. 50%) by about 2.5 ka, after which frequencies gradually decrease to modern levels. This spruce pollen increase is seen at a number of sites and suggests a transient northward and altitudinal treeline shift (Lamb, 1985; Short and Nichols, 1977).

Lastly, in the Arctic Archipelago, the mid- to late Holocene pollen records from Banks Island (Figures 1 and 6) document slight changes in vegetation. About 7 ka, the cores indicate higher proportion of local (birch) and long-distance (alder) shrub pollen, suggesting vegetation was probably shrubbier than today at least in the southern part of the island. After about 2–3 ka, shrub pollen frequencies generally decreased, and the vegetation reverted to a sedge-dominated tundra (Gajewski and MacDonald, 2004).

On Baffin Island (Figures 1 and 6), the middle to late Holocene vegetation began with relatively shrubby vegetation, with willows, birches, and ericads being the dominant shrubs. Sites in the southern part of the island also record significant increases in alder pollen (Iglutalik; Figure 6), but it is unlikely that it ever reached the island. Later, by about 4–3 ka, shrubs may have become less common, as some sites record reduced birch and willow pollen during the late Holocene (Short et al., 1985).

Discussion and Conclusions: LGM and Holocene Thermal Maximum Vegetation

Last Glacial Maximum

The LGM was the coldest part of the last Ice Age, centered about 21 ka, which generally corresponds with the period of greatest ice advance (Dyke, 2004; Dyke et al., 2002). Sea level was depressed by about 125 m, exposing the Bering Land Bridge and the continental shelf. One consequence of this change is sites that are near the coast today would have had a much more continental climate during the LGM. General circulation models indicate that both summer and winter temperatures in unglaciated Alaska and Yukon were 2–5 °C cooler than modern, sharply decreasing toward the east and the Laurentide Ice Sheet (Braconnot et al., 2007). Insect and pollen-based reconstructions are roughly similar to the model simulations. Chironomids (an aquatic insect) suggest that summer air temperatures were 2–4 °C cooler than modern in western Alaska (Kurek et al., 2009). Beetle-based reconstructions are somewhat variable, with summer temperatures about as warm as today at some sites (Seward Peninsula) and others significantly colder (up to 7 °C colder in the Yukon). A pollen-based reconstruction using the modern analog technique suggests summer temperatures were about 4 °C cooler and winter temperatures about 2 °C cooler (Viau et al., 2008).

The climate models also indicate increased aridity during the LGM with greatest aridity toward the margins of the ice sheet (Braconnot et al., 2007). Extensive dune fields, increased loess production, and near absence of lakes in unglaciated

Alaska and Yukon support the model results (Hopkins et al., 1982; Muhs et al., 2003).

Vegetation reconstructions during the LGM are at the center of a long-standing controversy (Hopkins et al., 1982). Pollen-based reconstructions tend to focus on the very low pollen influx (almost two orders of magnitude less than the Holocene) (Ritchie, 1984) and the abundance of herb and forb pollen. This suggested to researchers that there had been a very sparse graminoid vegetation, and in places, a polar desert (Anderson et al., 2004). The difficulty is that the quantity of bones from large grazers (mammoth, bison, and horse) from this interval implies a vegetation that was richer and more diverse than indicated by the pollen records (Guthrie, 1990). This apparent contradiction is somewhat resolved with high-resolution dating studies, indicating that mammoths, anyway, were more abundant before and after the LGM than during the LGM (Guthrie, 2003), and by vegetation modeling efforts, suggesting that the graminoid vegetation could have been more productive during the LGM than it is today, especially in central and western Alaska (Allen et al., 2010).

Central to the controversy is how to interpret the grass, sedge, and *Artemisia* pollen; this combination of taxa is not seen in today's vegetation. Pollen analysis cannot determine grass and sedge pollen to anything finer than the family level. As a result, those taxa are difficult to interpret in terms of vegetation or climate. *Artemisia* pollen is also somewhat problematic because in the north there are *Artemisia* species with steppic affinities and others with tundra affinities. Macrofossils recovered in the Yukon indicate the steppic taxon (along with other steppic plants) grew there during the LGM, but there is no indication that it grew in sites farther west. Other indicator taxa (species with specific environmental preferences that can be identified in the pollen record) can help with interpreting the pollen record. For example, many records contain weedy taxa which are typical of disturbed soils, suggesting that the LGM vegetation was not a continuous plant-covered surface but was probably pocked by areas of sediment, as is typical for high-latitude localities today (CAVM Team, 2003). Or, as noted above, *Thalictrum*, a relatively mesic taxon, is more common in the west than in the east, suggesting a moisture gradient during the LGM. While no exact modern analog of LGM vegetation exists today, analyses using plant functional types (vegetation classifications based on plant phenology (deciduous vs. evergreen), leaf morphology (broad leaf vs. needle leaf), life form (tree, shrub, or herbaceous), and climatic tolerances) indicate the closest modern biome is today found in disjunct locations across the northern tundra where shrubs are highly reduced and graminoid and forb taxa dominate (Bigelow et al., 2003).

Despite the widespread presence of herbaceous taxa during the LGM, trees may have been present in refugia. Evidence is accumulating that conifers were present in the Yukon just prior to the onset of the LGM (Zazula et al., 2006b) and in eastern Siberia (albeit a shrubby pine) during the LGM (Anderson et al., 2010). Although LGM-aged conifer macrofossils are yet to be found in Alaska or the Yukon, low (5% or less) but consistent spruce pollen (Figure 3) as well as the pattern of expansion during the Holocene suggest it may have survived the LGM in cryptic refugia (Brubaker et al., 2005). In addition, DNA analyses of white spruce in North America suggest that

populations growing today in unglaciated Alaska and the Yukon are significantly different from southern populations, suggesting they have been isolated from each other over glacial intervals (Anderson et al., 2006a).

Holocene Thermal Maximum

Many of the records discussed above document vegetation shifts which may be the result of warmer than modern climate during the Holocene. This includes the *Populus* expansion in Alaska, spruce treeline changes in the Northwest Territories, western Alaska, and eastern Canada, as well as shifts in shrub abundance in Arctic Canada. However, these shifts are not contemporaneous; they occur earlier in the west (early Holocene) and later in the east (middle to late Holocene) (Kaufman et al., 2004).

During the first half of the Holocene, due to variations in the Earth's orbit around the Sun, the amount of solar radiation reaching the high latitudes was greater than modern during the summer but less than modern during the winter. In the early Holocene, climate models suggest that because of this shift, temperatures were as much as 4 °C warmer than modern in summer and 2–4 °C cooler than modern in winter (Kutzbach et al., 1998), although by the middle Holocene, these anomalies had relaxed to about 1 °C warmer in summer and 1 °C cooler in winter (see PMIP2 website below). Pollen-based climatic reconstructions for the middle Holocene (6 ka) suggest a fair amount of variability across the north, although summer heat (measured as growing degree days) was generally higher than today, especially in northeastern Canada (Bartlein et al., 2011).

Spruce expansion on the Tuktoyaktuk Peninsula in northwest Canada (Ritchie et al., 1983) and north coastal Seward Peninsula in western Alaska (Wetterich et al., 2012) suggests ameliorating climate. The treeline shift on the Tuktoyaktuk Peninsula is about 30–40 km, whereas the Seward Peninsula spruce twig is about 100 km beyond the modern treeline to the east. However, it seems most likely that the Seward Peninsula spruce derived from a small population on the Bering Land Bridge. A pollen record from St. Paul Island on the southern land bridge records elevated spruce pollen percentages about 12 ka (Colinvaux, 1981) and no spruce wood has yet been recovered elsewhere on the Seward Peninsula (Hopkins et al., 1981) that would indicate a range expansion from the modern spruce limits to the east. The presence of spruce at both the Tuktoyaktuk Peninsula and the Seward Peninsula suggests about a 2–3 °C increase in summer temperature (Wetterich et al., 2012; Kaufman et al., 2004). As both sites are near the coast today, they would have been affected by lower sea levels as well as changes in insolation during the Holocene Thermal Maximum (HTM), both of which would have led to increased continentality and warmer summers.

The early Holocene *Populus* woodland of Alaska and the Yukon is a unique vegetation not found in the north today. This deciduous vegetation was mirrored in eastern Siberia, although the Siberian woodland included larch (a deciduous conifer) instead of *Populus* (Edwards et al., 2005). The expansion of these deciduous trees during the HTM may reflect not only warm springs as noted below but also the relatively cold

winters, because both these taxa tolerate very cold temperatures. Today, in Alaska, *Populus* can be found north of the spruce limit, and in eastern Siberia, larch forms treeline.

Macrofossil evidence from the north slope of the Brooks Range suggests it was cottonwood (*P. balsamifera*) that expanded during the HTM, at least in that region. Cottonwood reacts favorably to warm springs, and this partially explains its expansion (Kaufman et al., 2004). However, other factors may have been equally important. *Populus* may have been limited earlier by a lack of available substrates. Cottonwood is an early successional species found today mainly on aggrading floodplains. A careful study of drainage histories in the central foothills of the Brooks Range indicates widespread alluviation contemporaneous with the *Populus* expansion as well as downcutting and reduced *Populus* presence (Mann et al., 2002, 2010).

Treeline expansion in the eastern Northwest Territories, which was glaciated until about 8 ka, dates to the mid-Holocene (Queen's Lake and others), at the same time that lake productivity increased (Gajewski and MacDonald, 2004). Radiocarbon-dated buried forest soils west of Hudson Bay (deglaciated about 6 ka) indicate a 250 km northward extension of treeline about 4 ka (Sorenson et al., 1971), although pollen records to the north and west do not register this shift (Gajewski and MacDonald, 2004; Seppä et al., 2003).

Increased shrub abundance in the eastern Canadian Arctic (especially southern regions) dates to the middle and late Holocene, and sites on southern Baffin Island probably indicate local expansion of birch, although stronger or more frequent southerly winds blowing pollen from the south cannot be excluded. Pollen-based climate reconstructions (alder and boreal taxa excluded from the analysis) indicate summers were 1–2 °C warmer than modern (Kerwin et al., 2004).

Treeline sites in northern Québec and Labrador document modest HTM vegetation shifts. In Québec, treeline was apparently no farther north than it is today, but the forest-tundra ecotone of the middle Holocene may have more trees than today (Gajewski and MacDonald, 2004); temperature reconstructions suggest summers were less than 1 °C warmer than today (Kerwin et al., 2004).

The time-transgressive nature of the HTM is due in part to the presence of the Laurentide Ice Sheet over much of northern Canada (Kaufman et al., 2004). Ice Sheets affect climate both regionally (large-scale circulation effects) and locally (cold wind and/or water draining the ice sheet) (Bartlein et al., 1991). As the Laurentide Ice Sheet thinned, atmospheric circulation would have taken on its modern configuration, and local effects would have been time-transgressive across the region as the remaining ice melted. This may explain the evidence for cooling within an overall warming trend. For example, one of the most dramatic local effects was the draining of the large Laurentide proglacial lakes and resulting cold water flush into the North Atlantic at about 8.2 ka (Barber et al., 1999). This short (less than 1000 yr), sharp climatic reversal is seen only in one pollen diagram (Seppä et al., 2003) probably because sites that would have been closest to the cold flush would have either been covered by ice or by the proglacial lakes themselves. The vegetation recovery was rapid, however, and evidence of HTM warming returned with the continued expansion of shrubs and trees.

In sum, the HTM is a time-transgressive episode controlled by a combination of insolation changes and the timing of deglaciation. Pollen records document these changes by transient increases of tree and shrub pollen, which occur during the early Holocene in the west and the middle to late Holocene to the east.

Conclusions

Pollen, because it is widespread and generally identifiable to the genus level, is a robust means of reconstructing past vegetation, and the pollen records summarized above provide vegetation reconstructions spanning the past ca. 125 ka. During that interval, climate has been both colder (MIS 4, MIS 3, and MIS 2) and warmer (MIS 5 and HTM) than modern. During warm periods, trees and/or shrubs grew farther north than they do today. During cold periods, trees and most shrubs virtually disappear, leaving a herbaceous vegetation. Pollen data also record changes in plant productivity, with low pollen abundance (e.g., during the LGM) reflecting relatively sparse vegetation cover.

Pollen data are most robust when compared with other proxy records, especially plant macrofossils. Pollen, because it travels widely and because of variations in pollen production and preservation, sometimes results in a biased vegetation reconstruction. This is particularly true at treeline and in the tundra where both long-distance pollen and low local pollen production can be a problem. For example, the presence of spruce needles at Sleet Lake (Figure 5) during the HTM definitively documents that the spruce limit had expanded northward and it was not just a wind shift that brought increased spruce pollen to the site. In addition, in cases where plants are near their ecophysiological limits and are reproducing only vegetatively, the pollen record may underestimate the abundance of a taxon. This is probably the case during the Late Glacial of Alaska and the Yukon when birch pollen is so rare. In this case, even though there are no birch macrofossils, the rapid birch expansion with climatic amelioration suggests it was already present but not pollinating.

General Setting of South America for Paleoecological Studies

The late Pleistocene is taken here to cover the last ~130 000 years (130 ka) and includes the last and the present interglacial, separated by the last glacial. Many pollen records showing vegetation dynamics reflect the Holocene and the Late Glacial interval. Several records also reflect older parts of the last glacial, and only in a few sedimentary basins in South America, mainly in the Colombian Andes, can pollen records that represent the full late Pleistocene be retrieved. On a continental scale, multisite paleoecological results were summarized by Flenley (1979), Markgraf (1993), and Morley (2000). Multisite studies of more regional importance include Marchant et al. (2001), Van der Hammen and Hooghiemstra (2000), and Heusser (2003).

The South American continent includes nearly all biomes: from the wettest rainforest in Pacific Colombia (Chocó) with over 12 000 mm annual precipitation to extremely dry conditions in the Atacama Desert with less than 100 mm annual precipitation; from Amazonian forest types, ranging from evergreen to raingreen (semideciduous) and dry forest, to cold and wet páramo in the northern Andes, dry puna in the Central Andes, and wet Magellanic moorlands in Patagonia. Aspects of biogeography and late Quaternary history have been covered by Prance (1982), Prance and Lovejoy (1985), Vuilleumier and Monasterio (1986), Whitmore and Prance (1987), and Markgraf (2001).

Long Pollen Records, Biome Evolution, and Nonanalog Vegetation Communities

The Eastern Cordillera of Colombia includes remarkably deep basins, where, during long intervals of the Pleistocene, subsidence maintained the equilibrium with sediment infill. The altitudinal position of the surface of these basins (~2550 m) is half the amplitude of the altitudinally shifting upper forest line (UFL) during a glacial–interglacial cycle, viz. from around 3200 m at the present day to about 2000 m during a glacial (Figure 1). Along the altitudinal gradient, distinct vegetation belts can be recognized (Van der Hammen, 1974): tropical lowland forest from 0 to 1000 m, sub-Andean forest (=lower montane forest) from 1000 to 2300 m, Andean forest (=upper montane forest) from 2300 to 3200 m, dwarf forest and shrub in the subpáramo from 3200 to 3500 m, grass-páramo from 3500 to 4200 m, and superpáramo from 4200 to 4800 m (Figure 2). Each altitudinal belt is characterized by a distinct flora that has left identifiable pollen grains in the sediments. Downcore changes in the proportion of pollen grains originating from different vegetation belts show altitudinal shifts of those belts.

Most important are the basins of Fúquene (5°27'N, 73°46'W, 2580 m) and Bogotá (4°50'N, 74°12'W, 2550 m); which are located some 100 km apart. Constructing a robust timeframe for these mainly lacustrine sediments is difficult, and interpretations have changed over time. The pollen record from the almost 600-m-deep Bogotá basin starts some 3 Ma (e.g., Andriessen et al., 1993; Torres et al., 2005) but ends around 30 ka when the paleolake Bogotá drained. The depth of the Fúquene basin, separated from the Bogotá basin by a watershed of 3200 m altitude, is unknown, and so is the age of the oldest sediments. But sediments have continued to be deposited in Lake Fúquene up to the present time. Therefore, the last 30 ka of the pollen-based history of vegetation and climate change, not present in the Bogotá basin, can be found in the sediments of Lake Fúquene.

From these long Pleistocene records, we know that during the late Pleistocene, montane forests and páramo vegetation of the northern Andes have had a long and dynamic history, characterized by many repetitive climatic cycles and immigration events. The north Andean flora received trees migrating from the south (e.g., *Polylepis*, an Austral-Antarctic element) and from the Northern Hemisphere (e.g., *Alnus* and *Quercus*, both Holarctic elements). On timescales of several millions of years, the pollen record shows a continuum of change, driven by geological changes (e.g., tectonic changes in the basin and closure of the Panamanian Isthmus), evolution of ecosystems, and global climate change. As a consequence, late Pleistocene ecosystems are the product of a long history of change. The prelude of the late Pleistocene is documented in the pollen records of the 357-m-deep core Funza-1 and the 586-m-deep core Funza-2, plotted after the 2005 chronology (Torres et al., 2005 and unpublished data). The precise interpretation of pollen records is based on calibration sets of recent pollen rain (Figure 3). Moss samples collected along an altitudinal transect are prepared in the same way as the samples making up a pollen diagram. The results (Figure 4) show a clear relationship between the modern dominant pollen taxa and altitude. This relationship is applied to intervals of the past, assuming this relationship remains valid. This assumption should be treated with caution: the long pollen record of Funza has shown that many north Andean forest communities of the past do not have a modern analog. Also, the páramo vegetation composition during an interglacial setting (during full Quaternary time, this setting prevailed over ~10% of the time only) seems different from the vegetation composition during glacial conditions, when both low temperatures and low atmospheric carbon dioxide (CO₂) concentrations (low *p*CO₂) prevailed (Boom et al., 2001).

A molecular paleobotanical study of sediments from the Bogotá basin led to the hypothesis that the altitudinal distribution of C₃ and C₄ plants during modern time differs from that during glacial times (the hypothesis was formulated for

Figure 1 Altitudinal distribution of main vegetation belts in the Colombian Andes for the present day and the Last Glacial Maximum (LGM). Modified from Van der Hammen T (1974) The Pleistocene changes of vegetation and climate in tropical South America. *Journal of Biogeography* 1: 3–26; Wille M, Hooghiemstra H, Behling H, Van der Borg K, and Negret AJ (2001) Environmental change in the Colombian subandean forest belt from 8 pollen records: The last 50 ka. *Vegetation History and Archaeobotany* 10: 61–77.

Figure 2 Photographs of distinct vegetation belts: (a) superpáramo, (b) grasspáramo, (c) subpáramo, and (d) Andean forest.

the Last Glacial Maximum (LGM; **Figure 5**)). Under modern conditions, C_4 plants (herbs resistant to dryness and, potentially, photosynthesis, do not suffer from low pCO_2) occur at low elevations (below ~ 2000 m) in the inter-Andean valleys (dry because of a strong effect of the rain shadow) and the savannas. However, during glacial times, C_4 plants had a

competitive advantage over C₃ plants (including all trees and many herbs) and migrated upslope. As a consequence, it is hypothesized that the present-day páramo vegetation, dominated by C₃ herbs, was dominated by C₄ herbs, including *Sporobolus lasiophyllus*, which is rare in the modern páramo, during the LGM (Boom et al., 2001; 2002). Although results have to be

Figure 3 Modern pollen rain. Changes in pollen representation of surface samples in altitudinal intervals of 100 m. The present-day altitudinal range of the taxa is shaded. Reproduced from Van't Veer R and Hooghiemstra H (2000) Montane forest evolution during the last 650,000 years in Colombia: A multivariate approach based on pollen record Funza-I. *Journal of Quaternary Science* 15: 329–346.

confirmed, here is another example that past vegetation communities may reflect nonanalogs of present-day vegetation.

The geologically recent immigration of oak (*Quercus*) into South America is most relevant for the late Pleistocene of northern South America (Hooghiemstra, 2006). This Northern Hemisphere tree migrated into South America when the Panamanian Isthmus formed, around 4 Ma. Oak migrated slowly and arrived in the area of the Bogotá basin around 475 ka (Van't Veer and Hooghiemstra, 2000). A zonal belt with oak forest developed after 330 ka. During the period 220–135 ka, zonal *Quercus* and *Weinmannia* forests partly replaced *Podocarpus*-dominated forest. *Quercus* possibly spread southward in the sub-Andean forest belt, using the north–south oriented valleys of the Magdalena and Cauca rivers. At several places, *Quercus* could easily have expanded upslope and reached inter-Andean plains, such as the high plains of Bogotá and Fúquene. Today, the southernmost extension of *Quercus* is at the Colombian–Ecuadorian border, indicating a relatively low migration speed.

Late Pleistocene Dynamics of the Northern Andes

From the northern Andes, pollen records are available that show the dynamic history of vegetation change with great detail and the inferred sequence of climate change. Pollen

record Fúquene-2 (Van Geel and Van der Hammen, 1973) shows the interval from ca. 32 ka to the present with a temporal resolution of 300 years (Figure 6). The partly overlapping pollen record Fúquene-7C (Mommersteeg and Hooghiemstra, 2007) shows the interval from ca. 88 ka to the present with an average temporal resolution of 450 years. Seven carbon-14 (^{14}C) ages provide chronological control for the upper 40 100 calendar years before present (cal years BP), and the relationship between orbital forcing and lake-level stands was used to provide the chronology for the lower part of the record (Mommersteeg and Hooghiemstra, 2007).

Ten main intervals were identified and were related to the chronostratigraphy of marine isotope stages (MIS): 88.5–84.0 ka (MIS 5b), 84.0–70.5 ka (MIS 5a), 70.5–64.0 ka (MIS 4), 64.0–58.0 ka (MIS 4), 58.0–47.0 ka (MIS 3.3), 47.0–38.0 ka (MIS 3), 38.0–26.8 ka (MIS 3.1), 26.8–16.4 ka (MIS 2), 16.4–8.0 ka, and 8.0–6.3 ka. The UFL shifted between 2000 and 3300 m, and the inferred temperature depression varied from 1.5 to 2.0 °C at MIS 5.1, 3.0 to 4.0 °C at MIS 4, 1.0 to 2.0 °C at MIS 3.3, 2.5 to 4.0 °C at MIS 3.1, and 4.5 to 8.0 °C at MIS 2 (LGM); temperatures were similar to present-day temperatures during 8.0–6.3 ka. Precipitation change is inferred from forest composition and lake-level changes. This pollen record shows that forest near the UFL was dominated by *Quercus* (e.g., from ca. 60 to 47 cal years BP), and *Polylepis* (e.g., from ca. 47 to 36 cal years BP) in an alternating manner.

Figure 4 Main pollen diagrams of cores Funza-1 and Funza-2 from the sedimentary basin of Bogotá (Colombia) showing how late Pleistocene vegetation and climate change was preceded by a long series of Pleistocene ice ages. Reproduced from Torres and Hooghiemstra, unpublished data.

In the case where climatic conditions are centrally in the ecological envelope of a taxon, a given change in climate conditions may have less effect than in the case (for another taxon) where climatic conditions are marginal and close to the limits of the ecological envelope (Thompson et al., 2000). In other words, a central position in the ecological envelope may cause a low sensitivity to climate change while the same amount of change may cause significant vegetation change in a marginal position or even force a taxon to disappear. Therefore, individual taxa respond to environmental change, but as vegetation belts have many taxa in common that respond

almost similarly, vegetation belts too seem to respond as a quasi-unit. The significant difference between *Polylepis*-dominated and *Quercus*-dominated forests in pollen records of Fúquene-7C suggests that floristic changes in the composition of ecotone forest may also occur (partly) independently of climate change. This pollen record suggests a sensitive balance between altitudinally organized competing ecosystems. It shows that minor changes in temperature conditions at millennial timescales are clearly reflected when the examined natural archive lies at a strategic position and temporal resolution is adequate. Main periodicities of climate-forced

Figure 5 Altitudinal vegetation distribution in the area of the basin of Bogotá, Colombia. (a) Present-day vegetation belts; (b) multisite-based reconstruction of vegetation distribution during the LGM; (c) present-day altitudinal distribution of plants with a C₃ and C₄ photosynthetic metabolism: páramo vegetation is dominated by C₃ herbs; (d) tentative reconstruction for the LGM of maximum possible extent of C₄ grass distribution when $p\text{CO}_2$ is reduced to 180 parts per million V: páramo is tentatively dominated by C₄ herbs. Reproduced from Boom A, Marchant R, Hooghiemstra H, and Sinneghe Damsté JS (2002) CO₂- and temperature-controlled altitudinal shifts of C₄- and C₃-dominated grasslands allow reconstruction of paleo-atmospheric $p\text{CO}_2$. *Palaeogeography, Palaeoclimatology, Palaeoecology* 177: 151–168.

Figure 6 Main pollen diagram of core Fúquene-2 and core Fúquene-7C showing vegetation changes during the last 88000 cal years. During late glacial time, core Fúquene-7C has a hiatus and the Younger Dryas climate oscillation is reflected only in core Fúquene-2. Reproduced from Mommersteeg H and Hooghiemstra H (2007) Millennium-scale climate variability in the tropics from 88,000-yr pollen record Fúquene-7C (Colombia). *Journal of Quaternary Science*.

vegetation change, shown by the UFL record in particular, are concentrated in the 1000–4250-year frequency band.

An evaluation of the forest dynamics from pollen sites below 2000 m altitude indicated the degree to which modern vegetation belts were displaced and compressed during the LGM in the southern Colombian Andes (Table 1; Wille et al., 2001).

Considering the full altitudinal range of montane forests, the lower montane forest belt experienced the greatest compression during the last interglacial–glacial cycle; during the LGM, its altitudinal span was only 600 m, compared to 1300 m today. Although the lower limit of the lower montane forest belt is less clearly defined than its upper limit, the vertical interval is estimated at 55% of the present day; the difference in surface area is highly dependent on the locality under consideration. The salient ecophysical factor at the transition from the sub-Andean to the Andean forest belt is the occurrence of night frost; a few frosty nights may exclude frost-sensitive species and may have a decisive impact on the composition of the

vegetation. As a consequence, an explanation of the vertical vegetation distribution should be based more heavily on the ‘average temperature of the coldest month’ than on the frequently used ‘average annual temperature.’ This is a recommendation for the use of the ‘biome method’ (Prentice et al., 1992; elaborated for Colombia by Marchant et al., 2001) rather than the ‘Holdridge system’ to classify tropical ecosystems on ecophysiological grounds.

From phytogeographical studies, it became clear that the sub-Andean forest belt received many taxa from northern and southern latitudes by migration and from high and low elevations by adaptation (Van der Hammen and Cleef, 1986) and that it is floristically richer than the Andean forest belt. This high diversity coincides with a highly dynamic history on Quaternary timescales (Table 1). In the northern Andes, there are more coincidences between high diversity and a highly dynamic ecosystem. For example, the geologically youngest part of the Colombian Andes, namely, the Cocuy area in the Eastern Cordillera, shows the highest diversity of plants in the Espeletiinae group (Hooghiemstra et al., 2006; Van der Hammen and Cleef, 1986). Also, the páramo ecosystem is a good example of a biome with a very dynamic Pleistocene history coinciding with high species diversity: Figure 7 shows the archipelago of isolated páramo ‘islands’ on the highest mountain tops during modern (interglacial) conditions and extended areas with páramo vegetation during glacial intervals. Thus, periods of isolation (during ~20% of Pleistocene time), permitting allopatric speciation processes, are interrupted by periods with extended areas of páramo vegetation permitting

Table 1

Vegetation belt	Modern range (m)	LGM range (m)	Compression (%)
Tropical lowland forest	0–1000	0–800	~20
Lower montane forest	1000–2300	800–1400	~55
Upper montane forest	2300–3200	1400–2000	~33
Subpáramo, grasspáramo	3200–4200	2000–3000	~0

Figure 7 Extension and distribution of páramo during present-day and LGM conditions. The present setting reflects maximum isolation whereas the glacial setting offers opportunities for genetic material to be distributed over large areas. Reproduced from Van der Hammen T and Cleef AM (1986) Development of high Andean páramo flora and vegetation. In: Vuilleumier F and Monasterio M (eds.) *High Altitude Tropical Biogeography*, pp. 153–201. New York: Oxford University Press.

gene flow (during ~80% of Pleistocene time). The glacial-interglacial rhythm of expansion and contraction of the páramo area is considered an important mechanism to explain the high diversity of the high-Andean flora.

Pollen Record from the Colombian Savannas

The history of the savanna biome is best documented in the savannas of the Llanos Orientales in northeastern Colombia. This savanna area extends into Venezuela and represents the largest savanna ecosystem in northern South America (Huber, 1987; Huntley and Walker, 1982; Mistry, 2000; Sarmiento and Monasterio, 1975). Precipitation regimes are distinctly seasonal, related to the annually migrating Intertropical Convergence Zone (ITCZ), the main mechanism that brings seasonal variability in this ecosystem (Haug et al., 2001). Fires are frequent in the dry season and many trees have developed corky bark as a protection for fire (Mistry, 2000). Forest is mainly located in narrow corridors along the drainage system, forming gallery forest, and the higher elevations are covered by shrubby grasslands or pure grassland (Figure 8). Characteristic savanna trees are *Curatella americana* (Dilleniaceae), *Byrsonima crassifolia* (Malpighiaceae), and *Palicourea rigida* (Rubiaceae). Gallery forest shares many arboreal taxa with adjacent rainforests, but the palm *Mauritia flexuosa* is often abundant along streams and lake borders and forms characteristic palm forest (morichal). The open vegetation of the savannas is characterized by grasses. Many poaceous genera are represented in the savanna, but in paleoecological studies, pollen morphology does not distinguish between poaceous genera, and the proportion of grassy vegetation is reflected as one record.

Neotropical savannas occur north and south of the equator, separated by the Amazonian rainforest area where annual precipitation is minimally 1500–1800 mm and maximally a short (2 months), dry interval (Behling and Hooghiemstra, 2001; Van der Hammen and Hooghiemstra, 2000). Apart from climatic savannas, edaphic savannas also occur: these savannas lie on porous sandstone tablelands where the local vegetation is hardly able to make use of the abundant precipitation. A pollen diagram from such edaphic savanna is available

from the sandstone plateau of Araracuara, near the Caquetá River (Colombian Amazon). This pollen record shows that *Bonnetia* shrub with moraceous and melastomataceous trees alternates with open herb vegetation dominated by Rapatea-ceae, Poaceae, and *Xyris* (Berrio et al., 2003).

Figure 9 shows five pollen records from savanna lakes located along a 500-km east–west transect through the Llanos Orientales. They include Laguna Sardinas (4°58' N, 69°28' W, 180-m elevation), Laguna Angel (4°28' N, 70°34' W, 200-m elevation; Behling and Hooghiemstra, 1998), El Piñal (4°04' N, 70°14' W, 180-m elevation; Behling and Hooghiemstra, 2001), Laguna Loma Linda (3°18' N, 73°23' W, 310-m elevation), and Laguna Las Margaritas (3°23' N, 73°26' W, 290-m elevation; Wille et al., 2003). The openness of a savanna, indicating the degree of climatic humidity and the length of the dry period, is reflected in these pollen diagrams by the proportions of pollen of Poaceae, savanna shrub (*Byrsonima* and *Curatella*), and the group of elements of the gallery forest (from dry to more humid), respectively. Radiocarbon dates provide a robust time control and show that the full interval since the LGM is included. The general conclusions of these five pollen records and two additional pollen records from Laguna Carimagua (4°04' N, 70°13' W, 180-m elevation; Berrio et al., 2000) and Laguna Chenevo (4°05' N, 70°21' W, 150-m elevation; Berrio et al., 2002) are shown in Figure 10.

At the LGM, climatic conditions were very dry and these conditions continued up to the Late Glacial. Between ca. 10700 and 10070 ¹⁴C years BP (at El Piñal site up to 9200 ¹⁴C years BP), gallery forest had expanded, indicating less dry conditions. In all pollen records, the Holocene started between 9700 and 9200 ¹⁴C years BP with dry to very dry conditions that continued for several millennia. Climatic conditions became wetter between 7100 and 6100 ¹⁴C years BP in the western section of the savanna area close to the foothills of the Cordillera, and between 6400 and 5300 ¹⁴C years BP in the eastern section.

All pollen records show another increase in climatic humidity in the short interval between 4000 and 3600 ¹⁴C years BP. A southward migration of the average position of the ITCZ possibly supplied more moisture from the Atlantic Ocean to these latitudes (Brenner et al., 2001; Haug et al., 2001; Marchant and Hooghiemstra, 2004), causing drier climates in the

Figure 8 Schematic cross-section through the Colombian savanna area showing the relationship between landscape topography, drainage system, and vegetation. Figure 9 Main pollen diagrams of five sites located on a transect through the savanna of the Llanos Orientales in Colombia. From left (east) to right (west) are shown Lake Sardinas, Lake Angel, Lake El Piñal, Lake Las Margaritas and Lake Loma Linda. Reproduced from Berrio JC, Hooghiemstra H, Behling H, Botero P, and Van der Borg K (2002) Late-Quaternary savanna history of the Colombian Llanos Orientales from Lagunas Chenevo and Mozambique: A transect synthesis. *The Holocene* 12: 35–48; Behling H and Hooghiemstra H (2000) Holocene Amazon rain forest-savanna dynamics and climatic implications: High resolution pollen record Laguna Loma Linda in eastern Colombia. *Journal of Quaternary Science* 15: 687–695; Wille M, Hooghiemstra H, Van Geel B, Behling H, De Jong A, and Van der Borg K (2003) Submillennium-scale migrations of rainforest-savanna boundary in Colombia; ^{14}C wiggle-matching and pollen analysis of core Las Margaritas. *Palaeogeography, Palaeoclimatology, Palaeoecology* 193: 201–223, with permission.

Caribbean and moister conditions at more equatorial latitudes. Increased precipitation levels allowed *Mauritia* and *Mauritiella* palms, which were rare during the previous interval, to become abundant in the Llanos Orientales between 4000 and 3700 ^{14}C years BP. These palms formed extensive stands on soils with stagnating water. This climate-driven vegetation change may have coincided with the first human settlements in this savanna area. Expansion of settlements in the savannas was possibly also related to more favorable (wetter) climate conditions. Natural climate change forced vegetation change but may also have triggered expansion and migration of human populations, leaving mixed signals in pollen records which are often difficult to disentangle.

How Stable/Dynamic is the Amazonian Rainforest? The Pollen Evidence

The nature of the Ice Age vegetation of the Amazon remains highly controversial. Explanations of the huge biodiversity in the Amazonian rainforest are based on a variety of assumptions. The scarce data from diverse proxies (pollen, plant macrofossils, lake levels, paleodune fields, noble gases, stable isotopes, sediment sections, etc.) are interpreted in directions that best conform to these assumptions, hindering a quasi-objective, evidence-based interpretation of the available data. The papers by Colinvaux et al. (2000) and Van der Hammen

and Hooghiemstra (2000) are good reflections of the state of the art and convincingly indicate that more research at strategic sites is needed before a conclusive decision on Haffer's forest refugia hypothesis can be made. Logistically, the Amazonian rainforest biome is difficult to access for researchers. But it is even more important to find adequate sites that contain well-preserved pollen records (and other proxies) to document the dynamics of the Amazonian rainforest biome. The *terra firma* area, of relatively high elevation and never inundated by the Amazonian drainage system, has thus far offered few sites with pollen records. The low areas of Amazonia include the presently active drainage system and the wide river valleys that were filled with riverine sediments supplied by these drainage systems in the past, when these rivers had different courses. The latter explains the limitations of paleoecological research in the abandoned and now active parts of the river valleys: rivers were changing their courses continuously, preventing sites from accumulating sediments during long periods of time. Therefore, the few available pollen records from rainforest sites mostly come from abandoned meanders and rarely cover an interval longer than the Holocene. Once a pollen record from a rainforest area has been produced, there are practical problems: a significant proportion of the trees are palynologically 'silent,' that is, they do not produce large numbers of pollen grains because they are insect pollinated. Moreover, a large number of trees recognized by their pollen grains have undefined 'ecological envelopes,' hindering the ecological categorization of many

Figure 10 Synthesis of environmental change in the savannas of the Llanos Orientales in Colombia from seven sites reflecting the last 18,000 years. From left (east) to right (west) are shown Laguna Sardinas, Laguna Angel, Laguna El Piñal, Laguna Carimagua, Laguna Chenevo, Laguna Loma Linda, and Laguna Las Margaritas.

records (each with low representation) that are needed to reconstruct details of environmental change.

Pollen records spanning longer intervals are located at the outer borders of the Amazonian rainforest: the Carajás site in southeast Brazil (Absy et al., 1991), and Lagunas Bella Vista and Chaplin in the Bolivian Amazon (Mayle et al., 2000). Site La Pata (Colinvaux et al., 1996) is the only pollen record that shows vegetation dynamics from the 'interior' of the rainforest during the Holocene and a significant part of the last glacial. Figure 11 shows the locations of the most important pollen sites. The centrally located site, La Pata, shows the continuous presence of forest, but that forest changed into a drier type during the LGM (Ledru et al., 1998). The marginally located sites, Carajás and Chalpin, show alternations between periods of forest (wet climatic conditions) and periods of dry vegetation (varying from dry forest to savanna). Interestingly enough, these alternations in humidity in the marginal areas seem related to precession forcing of climate change.

The refugia hypothesis of Haffer (1969, 1982) postulates that during the LGM, the Amazon basin was covered with a significant surface of dry, savanna-like vegetation and rainforest had retreated to a number of isolated refugia. This theory is neither validated nor adequately rejected by fossil data. There is

progress in understanding speciation processes. Apart from the classical mechanism of allopatric speciation, sympatric speciation is a process that stimulates thinking in terms of forest refugia. This kind of speciation is now widely accepted as a relevant mechanism to understand how the Amazonian rainforest could have reached such high levels of biodiversity. In general, precipitation change has a more severe effect on rainforest composition and distribution than low-scale temperature change (estimates for the LGM temperature cooling in Amazonia vary at 3–6 °C; Farrera et al., 1999). The main forcing factor for moisture change, brought about by orbitally forced migrations of the ITCZ, is a stable factor of the climate system. Contrary to this, however, temperature change in Amazonia possibly increased greatly at the onset of Pleistocene ice ages. Therefore, it is doubtful whether Pleistocene climates of the Amazonian rainforest should be characterized as 'dynamic,' as is the case for the páramo biome.

Relatively basic problems in Amazonian paleoecology remain unsolved: there is much discussion on how the presence of pollen grains of cool montane trees (*Podocarpus* in particular) should be interpreted, in terms of LGM temperature. *Podocarpus* has important representatives in the cool Andes, but several species also inhabit Amazonian lowlands. As the

Figure 11 Map showing main pollen sites in and around the Amazonian rainforest area (sites 1–11) and the mean position of the ITCZ at the present day (a) and between 12 400 and 8800 cal years BP (b). Sites are (1) Serra dos Carajas, Brazil; (2) Lake Titicaca, Bolivia; (3) Lake Valencia, Venezuela; (4) São Gabriel da Cachoeira, Brazil; (5) Rio Caquetá, Colombia; (6) upper Rio Doce, Brazil; (7) Brasília, Brazil; (8) Atacama Desert, Chile; (9) Junin Plain, Peru; (10) Salitre, Brazil; (11) Araucaria forest area, Brazil. The shaded continental area delimits the zone of influence of the moist equatorial air masses (northeast trades) east of the Andes; warming of the continent during the austral summer induces a significant southward migration of the ITCZ. Reproduced from Martin L, Bertaux J, Corrège T, et al. (1997) Astronomical forcing of contrasting rainfall changes in tropical South America between 12,400 and 8800 cal yr BP. *Quaternary Research* 27: 117–122.

relation between climatic parameters and distribution of *Podocarpus* species is not well established, debates on the interpretation of *Podocarpus* peaks in pollen records continue (Behling and Lichte, 1997; Bush et al., 1990; Van der Hammen and Hooghiemstra, 2000). The cooperative initiatives between modelers and paleoecologists of the 1990s (Thompson et al., 2000) need to be followed up.

Understanding how the climate system operates is crucial to improve our interpretation of proxy records of environmental change. Martin et al. (1997) were able to explain the contrasting rainfall changes in tropical South America between 12 400 and 8800 cal years BP, clarifying a mechanism of more general importance for the tropical regions of South America. They compared Lake Titicaca (16°S, 69°W) in Bolivia with Lake Valencia (10°N, 67°W) in Venezuela. Between 12 400 and 8800 cal years BP, the water level of Lake Titicaca dropped gradually to 60 m lower than that today, indicating a large deficit in rainfall over the Altiplano. In contrast, during the same interval, Lake Valencia changed from an ephemeral lake to an overflowing lake. The present-day mean position of the ITCZ during the austral summer has a southern position, but between 12 400 and 8800 cal years BP the conclusive evidence from some ten sites and from insolation data shows that the mean position of the ITCZ was ~10° north of its modern position. This mechanism explains the antiphase rainfall relationship between Bolivian and Venezuelan latitudes, reflecting a migration of the ITCZ at the precession rhythm of orbital climate forcing. Precessional forcing also explains the presence of savanna with ca. 20-ka intervals in the pollen record of

Carajas (viz. around 65, 45, 25, and 6 ka BP) with intervals of wet forest in between (Absy et al., 1991).

Introduction

Pollen analysis is one of the most efficient tools for the reconstruction of past environmental changes. Southern Europe has yielded numerous key pollen sequences, some continuous over long time intervals. After discussing the history of paleoecological research and identifying major reference sections, we use these records to trace spatial and temporal vegetation variability through southern Europe during glacial–interglacial cycles, interpreting the records in terms of climate forcing, and discussing the major trends in Mediterranean biodiversity during the Pleistocene, with special attention to late Pleistocene.

History of Research

For northern and central Europe, the first pollen records that provided information on Pleistocene vegetation history were recovered from The Netherlands, Britain, Denmark, and Germany. These records provided a framework for understanding the vegetation history of Pleistocene interglacials. However, in northern Europe, repeated advances and retreats of ice sheets caused repeated sediment accumulation and erosion. As a consequence, the records are usually discontinuous in space and time and are often difficult to place in a stratigraphic context. In contrast, southern Europe contains some sites, such as subsiding basins or crater lakes (maars) in tectonically active regions that have the potential for continuous sediment accumulation over long intervals. The investigation of such sites (Figure 1) during recent decades provided information about vegetation and climate changes during several glacial–interglacial cycles and has opened the door to detailed correlations with other types of long records (loess sequences, deep-sea sediment cores, and ice cores).

Greece

The first long pollen sequence (and still the longest) described in southern Europe comes from a subsiding basin in Macedonia, northeast Greece: Tenaghi Philippon (Wijmstra, 1969). A 120-m core yielded sediments spanning more than 1 Ma. Wijmstra and his collaborators have devoted more than 25 years to the study of this record, which was one of the first in Europe showing many climatic cycles during the Pleistocene (van der Hammen et al., 1971; van der Wiel and Wijmstra, 1987a, 1987b; Wijmstra and Smit, 1976) in agreement with the Milankovitch (1930) theory and contrary to the ‘classical’ four-part glacial–interglacial scheme proposed by Penck and Brückner (1909). Tzedakis et al. (2003c) and Tzedakis et al. (2006) proposed a new chronology for this sequence, based on an initial alignment

with the marine $\delta^{18}\text{O}$ record, which was further refined by a direct pollen–orbital tuning procedure; according to this, the base of the sequence extends back to 1.35 Ma.

By correlating with the northern European pollen record, Wijmstra and colleagues were the first to demonstrate a latitudinal gradient in upper Pleistocene European vegetation dynamics. Oak forest played a major role during most of the interglacial, without the well-marked succession of forest trees characteristic of the mid-European interglacial sequences. Oak forests also succeeded in expanding during the post-Eemian (marine isotopic stage (MIS) 5e) interstadials when boreal forests were growing in northern Europe; the Macedonian interstadials Drama and Elevteroupolis were convincingly correlated with the Dutch interstadials Brörup and Odderade (MIS 5c and 5a, respectively). A new core recovered in 2005 will be subjected to a higher resolution multidisciplinary study (Pross et al., 2007).

The discovery of the Tenaghi Philippon record led other researchers to explore records from other subsiding basins, such as Ioannina (Bottema, 1974; Tzedakis, 1993, 1994), Xinias (Bottema, 1979), and Kopais (Okuda et al., 2001; Tzedakis, 1999). A new core from Ioannina, in northwest Greece, is being analyzed at much higher resolution (ca. 200 years). Results so far cover the last 130 ka (Tzedakis et al., 2002, 2003b), the penultimate glacial (Roucoux et al., 2011) and the penultimate interglacial complex (Roucoux et al., 2008). The forest phases are also characterized by early expansion of deciduous and evergreen oak (*Quercus* spp.) and Mediterranean sclerophylls but are followed by a more diverse vegetation succession compared to that inferred from the Tenaghi Philippon record. This diverse vegetation includes elm (*Ulmus*), hazel (*Corylus*), hornbeam (*Carpinus betulus*), fir (*Abies*), and beech (*Fagus*). The penultimate interglacial complex, corresponding to MIS 7, includes three major temperate intervals (Zitza I, Zitza II, and Zitza III, respectively, corresponding to substages 7e, 7c, and 7a). Of these, the longest and the warmest interval is Zitza II (Roucoux et al., 2008). At the end of Zitza I, an abrupt shift to colder and drier climatic conditions is observed, in agreement with the French Lac du Bouchet record (Reille et al., 2000).

In the northwest Balkan Peninsula (former Yugoslavia), there are regions, such as the Ljubljana plain, with a geological setting suitable for Pleistocene long sequences (Sercelj, 1966). However, the recent political situation has not allowed these areas to be investigated for their potential Pleistocene records. In Albania, after research initiated on Lake Malik (Denèfle et al., 2000), the multidisciplinary study of Lake Ohrid (704 m a.s.l.) (Lezine et al., 2010) provides a record of the last glacial–interglacial cycle in a mountain zone and complements the Greek sites.

Italy

Due to active neotectonic activity, several uplifted Italian marine sequences were used to define the Plio/Pleistocene boundary. The official stratotype for this boundary has been defined at Monte San Nicola, Sicily (Gibbard and Head, 2010), replacing the previous type site at Vrica (Aguirre and Pasani, 1985). A review of the other sections is available in Bertini (2003). Further north in Europe, the pre-Alpine site of Leffe (Figure 1), north of Bergamo, was first studied by Lona (1950) and Lona and Follieri (1957) and later reinvestigated by Ravazzi and Rossignol-Strick (1995) and Muttoni et al. (2007). This site provides an example of early Pleistocene climatic cycles spanning the interval 0.87–1.9 Ma in a region wetter than Tenaghi Philippon. These pollen spectra were dominated by tree taxa that today are extinct in Europe. These ‘Tertiary relicts’ include cedar (*Cedrus*), hickory (*Carya*), wingnut (*Pterocarya*), and *Eucommia*. The glacial intervals were short and not sharply defined, and the interglacials were rather wet. Close to Leffe, a thick annually laminated lacustrine sequence outcrops at Pianico-Sèllere. This interglacial complex, initially correlated with the last interglacial (MoscarIELLO et al., 2000), has been dated by the occurrence of the Brunhes/Matuyama boundary (marking a paleomagnetic reversal) at ca. 800 ka (Pinti et al., 2001). A controversy arose when Brauer et al. (2007a) attributed an age of ca. 400 ka to a tephra (volcanic ash) layer included in the section. Nevertheless, in terms of both palynostratigraphy and magnetostratigraphy (Roulleau et al., 2009; Scardia and Muttoni, 2009), this sequence cannot be contemporaneous with MIS 11, and the correlation with MIS 19 is more likely. Even by that time, the pollen data show that almost all the exotic (or Tertiary relic) trees had already disappeared. The timing of the vegetation succession was established by varve counting and high-resolution pollen analyses. The vegetation sequence is comparable with that of the last interglacial. The floristic differences between Leffe and Pianico are consistent with the vegetational changes characterizing the transition from the early to the middle Pleistocene.

A long core in the Venice lagoon (Massari et al., 2004) yielded a full Pleistocene record, but it provided results that are difficult to interpret due to phases of fluvial erosion by the Po River. Not far to the east along the Adriatic coast, a 95-m long core at Azzaro Decimo (Pini et al., 2009) provided a pollen record for the last 215 ka, unfortunately disturbed by several layers of sterile gravels resulting from fluvial activity. Lake Fimon (Pini et al., 2010), in the Berici Hills, west of Padova, provides also a detailed record of the last climatic cycle. The interval contemporaneous with MIS 5 is registered in 5 m of sediments, allowing the acquisition of a high-resolution pollen diagram. Vegetation dynamics during the last interglacial (corresponding to MIS 5e and the lower part of 5d Shackleton et al., 2003) is marked by the late arrival and relatively small contribution of European hornbeam (*C. betulus*) pollen and the relative abundance of beech (*Fagus*) during the later phase.

In southern Italy, south of Naples, the middle Pleistocene sequence of Vallo di Diano (Russo Ermolli and Cheddadi, 1997) includes two interglacials correlated with MIS 15 and 13.

During the 1980s, the intensive exploration of crater lakes and paleolakes from central and southern Italy yielded several long pollen records. Intensive studies at Lago Grande di Monticchio, well dated by tephra layers and by annual laminations, gave a detailed description of the vegetation and climate changes during the last glacial–interglacial cycle and suggested a duration of ca. 17 700 years for MIS 5e (the last interglacial interval) (Allen et al., 1999, 2009; Brauer et al., 2007b), in close agreement with the estimates from the Ioannina sequence based on tuning of pollen sequences to orbital forcing curves (pollen-orbital tuning) (Tzedakis et al., 2003b). Most of these sediment sequences do not extend beyond the last interglacial (see Pollen Records, Last Interglacial of Europe), except at Valle di Castiglione, where Follieri et al. (1988) obtained a pollen sequence for the last 270 ka. At this site, researchers first identified a phase of major expansion of Mediterranean

tree taxa such as olive (*Olea*), pistachio (*Pistacia*), and evergreen oak (*Quercus ilex*) at the beginning of the last interglacial. Here, pollen from mesophilous trees, such as hazel (*Corylus*), European hornbeam, beech, and fir (*Abies*), a major component of the pollen spectra. This is also the case for the two temperate episodes which follow MIS 5c and 5a and the three major temperate phases of the penultimate interglacial complex (Roma I, II, and III at Valle di Castiglione, which are equivalent to MIS 7e, 7c, and 7a). *Zelkova*, which had disappeared from continental western Europe during the middle Pleistocene, was still present on the Italian peninsula until the last Pleniglacial (MIS 2).

Spain

Unlike Greece, Spain, at the same latitude, is poor in Pleistocene records. The promising site of Padul ([Figure 1](#)) lies in a large tectonic depression in the foothills of Sierra Nevada, which contains a thick succession of peat and silt layers. The three pollen diagrams published by [Florschütz et al. \(1971\)](#) and [Pons and Reille \(1988\)](#) are difficult to interpret, partly due to poor pollen preservation in most of the peat layers ([Pons and Reille, 1988](#)), probably due to changes in the water table and desiccation phases. The pollen zone IVb (70–24 m) ([Florschütz et al., 1971](#)) shows two major temperate episodes (j and m, considered to predate the last interglacial) with abundant oaks (undifferentiated) alternating with dry phases characterized by dominant steppe with stands of pine, but the record's resolution is too low to allow a consistent correlation with the other Mediterranean long sequences. The interval between 24 m and 12 m in core IV, with an abundant warm flora alternating with dry episodes, is convincingly correlated by [Pons and Reille \(1988\)](#) with the interval 14.8 m–6 m in their core Padul 2, but they diverge in their interpretation which correlates this section with the early Würm (MIS 5c to 5a) contrary to [Florschütz et al. \(1971\)](#) who attribute the early temperate episode to the last interglacial (MIS 5a). Further studies and absolute dates are needed to refine the chronology at this site.

The few other Spanish sites providing information on the Pleistocene vegetation are in Catalonia. These include Banòles ([Pérez-Obiol and Julià, 1994](#)), with a detailed record of the last glacial, and Olot ([Burjachs, 1994](#)), with a partial record of the last interglacial (characterized by phases with abundant European hornbeam and fir).

Fortunately, pollen analyses of marine cores close to the Iberian coast provide an integrated perspective of long-term vegetation changes on the adjacent continent and, moreover, provide direct land–sea correlations. The first direct palynological correlation of MIS 5e with the Eemian interglacial was identified in a core from the Iberian margin ([Turon, 1984](#)), and provided a starting point for more intensive research. After a thorough study of the interglacial complex offshore the Tajo river catchments ([Sanchez-Goni et al., 1999](#)), a description of the last four glacial–interglacial cycles is now available from cores MD95-2039, MD01-2443, MD01-2444, MD01-2447, and MD04-2845 ([Desprat, 2005](#); [Desprat et al., 2006](#); [Margari et al., 2010](#); [Roucoux et al., 2011](#); [Sanchez-Goni et al., 2008](#); [Tzedakis et al., 2004b](#)). A characteristic of the cold phases on the Iberian coast is the abundance of Ericaceae. During MIS 5,

oaks are the dominant forest elements during the temperate intervals, and a marked occurrence of evergreen trees is inferred during an early phase of MIS 5e. The last glacial cycle is also registered in marine cores from the Alboran sea (ODP 076, MD95-2043) ([Combourieu-Nebout et al., 1993](#); [Combourieu-Nebout et al., 2002](#); [Sanchez-Goni et al., 2002](#)).

France

In contrast to the peninsulas of Spain and Italy, which are isolated from middle Europe by mountain ranges, the French Mediterranean lowlands are connected with continental Europe by the Rhône/Saone corridor. The Pleistocene vegetation was poorly documented in France till the 1970s. The discovery of la Grande Pile by Seret and [Woillard \(Woillard, 1978\)](#), the first west European site with a continuous record of the last glacial–interglacial cycle, formed an impetus for new investigations, leading to the discovery of its more southern counterpart of Les Echets ([de Beaulieu and Reille, 1984](#)). The two sites show forest dynamics during the last interglacial very similar to those of the classical Eemian (the same succession of forest types and same absence of beech). The early Würm interstadials (St. Germain I and II corresponding to MIS 5c and 5a) show complex forest successions including episodes of dominant mesophilous trees at a time when boreal forests expanded in the Netherlands and northern Germany (the Brörup and Odderade interstadials). This provides evidence of a steeper climatic gradient in Europe during this interval, compared with the Eemian and the Holocene. However, these results were so unexpected in 1975 that it was suggested that the St. Germain I and II layers at Grande Pile represented a massive redeposition of the last interglacial sediments. At Les Echets ([Figure 1](#)), two new cores recovered in 2001 provided additional information for the upper part of the sequence (last glacial) showing the local consequences of Heinrich events and Dansgaard–Oeschger events ([Verès et al., 2007](#); [Verès et al., 2009](#); [Wohlfarth et al., 2008](#)) and of the transition from the penultimate glacial to the last interglacial ([Gandouin et al., 2007](#)).

However, another major Pleistocene key sequence soon confirmed the records from Grande Pile and Les Echets. This came from the crater lakes and paleolakes of the Velay Plateau (Massif Central), a highland region close to the Mediterranean Cevennes, built up by volcanic activity from the Oligocene to the Late Glacial. The exploration of three maars, Lac du Bouchet, Ribains, and Praclaux ([de Beaulieu and Reille, 1992](#); [Reille and de Beaulieu, 1995](#); [Reille et al., 1998](#)), allowed the development of a composite pollen sequence which covers the four last glacial–interglacial cycles (i.e., the last ca. 450 ka) ([Reille et al., 2000](#)). Due to its location close to the 45th parallel, this record may be important as a link between the classical Mediterranean long sequences and the north European record. Below the last interglacial (see [Pollen Records, Last Interglacial of Europe](#)), four cold intervals (correlated with MIS 6, 8, 10, and 12) alternate with three temperate ‘complexes’ correlated with MIS 7, 9, and 11. As during MIS 5, each of the latter starts abruptly with a strong temperate interglacial (Bouchet 1 = MIS 7e, Landos = MIS 9e, Praclaux = beginning of MIS 11) marked by the classical succession of European forest trees. This vegetation sequence starts with pioneer trees, then warm mixed oak forests

expand and are replaced by less thermophilous trees (yew, hornbeam, and firs) and finally, boreal spruce and pine forests mark the end of the interglacial. The three main interglacials are followed by a succession of two or three short stadials (similar to Melisey 1 and 2, and contemporaneous with MIS 5d and 5b) alternating with two or three temperate or mild intervals as shown by the expansion of the less temperate deciduous trees and/or of boreal conifers. These intervals are reminiscent of the Saint Germain interstadials in MIS 5. In most cases, the initial interglacial is marked by an important development of warmth-demanding trees, which are increasingly less abundant during the subsequent interstadials. This gives a decreasing sawtooth structure to regional pollen curves which shows a striking similarity with the climate record inferred from Antarctic ice cores (Petit et al., 1999), illustrating a global interhemispheric signature (Figure 2).

Trends in Vegetation Dynamics

Mediterranean Climate Setting and Beginning of Ice Age

The gradual cooling which has occurred since the end of the Eocene is well documented in the pollen records from southern Europe. It began around 3.6 Ma with the initiation of climatic phases marked by summer aridity. This environmental stress promoted different adaptations among regional plant species, including a differentiation among the already existing sclerophyllous taxa, which evolved into the present-day Mediterranean flora (Comboureu-Nebout, 1993; de Beaulieu et al., 2005; Suc et al., 1995). However, Tzedakis (2007)

suggested that the Mediterranean-type climate is not exclusively a post-3.6 Ma phenomenon but may have appeared intermittently during the course of the Tertiary.

The early Pleistocene represents a transition between climate governed by subtropical environments toward regimes marked by an intensification of glacial cycles between 1 Ma and 800 ka. During this interval, several taxa that had persisted from the Tertiary flora were still abundant, although their role progressively decreased. The Leffe sequence (Ravazzi and Rossignol-Strick, 1995) presents an example of early Pleistocene 40-ka glacial cycles. The Jaramillo paleomagnetic event dates the upper part of this sequence to ca. 1 Ma. The pollen sequence shows seven glacial-interglacial cycles characterized by the same recurrent successions of vegetation types, with forests almost always dominant. Each cycle (Figure 3(a)) starts with a short phase of moderately open vegetation, with a maximum abundance of xerophilous herbs (sage (*Artemisia*) and other steppe elements), which is associated with a cold and dry episode associated with a glacial interval. Then deciduous trees expand, first oak, hazel, and hornbeam, followed by a maximum of Juglandaceae (hickory and wingnut), associated with hemlock (*Tsuga*), which corresponds to a warm and wet climatic optimum, finally the expansion of mountain conifers (pine, spruce, and cedar) correspond to a climate cooling. This is then followed by second broadly similar succession, with *Quercus*, *Ulmus*, *Carpinus*, and *Carya*, terminating in a prolonged coniferous phase, before the onset of a relatively short steppe vegetation phase. This suggests the persistent influence of precession in southern Europe even during the interval of obliquity-dominated glacial cycles (Tzedakis,

Figure 2 Comparison between the air surface temperature curve during the last 450 000 years at Vostok, Antarctica (based on the isotopic composition of the ice: from Petit et al., 1999) and the pollen curves of the sum of the most thermophilous trees in the Velay sequence (redrafted from Tzedakis et al., 1997). They show impressively similar saw-tooth structures. The slight differences in timing are, in great part, due to different age models.

Figure 3 Differences between vegetation cycles during the lower Pleistocene (a) and during middle/upper Pleistocene (b). From de Beaulieu J-L, Andrieu-Ponel V, Cheddadi R, et al. (2006) Apport des longues séquences lacustres à la connaissance des climats et des paysages pléistocènes. *C.R. Palévol* 5: 65–72.

2005). The pollen flora is rich in 'Tertiary' taxa such as Taxodiaceae, hemlock (*Tsuga*), cedar, and the deciduous hickory, wingnut, *Eucommia*, Persian ironwood (*Parrotia*), horse chestnut (*Aesculus*), and sweetgum (*Liquidambar*).

The lower part of Tenaghi Philippon record from ca. 1.35 Ma is contemporaneous with Leffe (Tzedakis et al., 2006). The main difference between the two sequences is the major role played by oak and Mediterranean pines at Tenaghi Philippon due to a drier climate.

Pleistocene Extinctions and the South European Refuges

The causes of the change from 40-ka cycles to 100-ka cycles (governed by orbital eccentricity), which became dominant during the first part of middle Pleistocene, are still unclear. The $\delta^{18}\text{O}$ curves from benthic Foraminifera in deep-sea cores clearly show that the MIS 22, at ca. 900 ka, is the first glacial episode marked by major ice accumulation and very low temperatures on the continents, as became the rule in the middle and late Pleistocene. As shown by the Italian sequences and, to a lesser degree, by Tenaghi Philippon, this glaciation was certainly an interval of major extinction for the most of the Tertiary temperate flora of Europe. After this episode, the Juglandaceae never played a major role in the vegetation, and this group declined in importance in the European vegetation as the more medio-European taxa (European hornbeam, beech, and spruce) became dominant.

The lower part of the middle Pleistocene (between the Brunhes/Matuyama boundary and ca. 450 ka) is poorly documented except at Tenaghi Philippon. This remains a unique European key site that provides a nearly continuous record of the past 1.35 Ma. At this site, Tzedakis et al. (2006) demonstrated that the cold period corresponding to MIS 16 represents

a second major period of extinction in Greece. Cedar, hickory, and *Eucommia* disappeared or became restricted to very small refuges and never again played a significant role in forest ecosystems. But at Pianico-Sèllere, in Northern Italy, these tree taxa were already absent by 800 ka, pointing to regional lags in the timing of local extinctions.

The history of the extirpation of the few remaining 'Tertiary relicts,' such as wingnut and *Zelkova*, from the European flora is well known. *Zelkova* was able to persist in central Italy until MIS 2 and two small, isolated populations still survive in Sicily and Crete (Quézel and Médail, 2003). This case illustrates the role of Mediterranean peninsulas in the conservation of temperate trees during glacial episodes. Recent studies linking paleoecology and phylogeography have shown that the location of refuges during the last glaciation constrained the distribution of forest ecosystems during the Holocene (Hewitt, 2000; Petit et al., 2002, 2003). This evidence must likewise be valid for the previous climatic cycles and may explain part of the variability in forest dynamics between the different interglacials.

Climatic Cycles and Orbital Forcing

On the basis of the Tenaghi Philippon record, Tzedakis et al. (2006) consider that the forest dynamics during all the interglacials following MIS 16 present common trends (of a 'modern' character) marked by episodes with abundant hornbeam in addition to oak (four hornbeam peaks between MIS 16 and MIS 12) and more frequent occurrences of fir. The two interglacials correlated with MIS 15 and 13 at Vallo di Diano are true to this model, also showing a great abundance of fir.

Following MIS 12, the spatial pattern of the glacial-interglacial cycles across southern Europe rests on the correlation between the five longest pollen sequences (Tenaghi Philippon, Velay, and valle di Castiglione and the deep-sea sediment cores off the Iberian Peninsula and from Alboran sea). In a first attempt at correlation, Tzedakis et al. (1997) developed a common chronology based on a tuning of the interglacial inceptions with the marine isotope timescale (Figure 4), which is mostly governed by orbital eccentricity and axial tilt. Later, a more detailed investigation led Magri and Tzedakis (2000) to identify direct relations between vegetation phases and precession cycles (Berger, 1977). An expansion of the Mediterranean taxa, pistachio (*Pistacia*), green olive (*Phillyrea*), and olive (*Olea*), generally at the beginning of most of the warm intervals, was correlated by Magri and Tzedakis (2000) with summer occurring at perihelion leading to arid summers. Later, the shift toward September perihelion was correlated with the maximum biomass of mesophilous forests. March perihelion is correlated with maximum extension of herbs. In light of this concept, Tzedakis et al. (2003a,b, 2006) reexamined the Greek sequences and adopted a timescale for Tenaghi Philippon that is slightly different from the one proposed in 1997. In any case, there is a striking correlation between the SPECMAP curves (Figure 4) and the succession of forested and nonforested episodes in the pollen sequences. This clearly demonstrates that each of the temperate intervals attributed to MIS 11, 9, and 7 is marked by a succession of climatic oscillations including cold stadials. Not less than 13 major warm phases are documented between MIS 12 and the

present (Figure 4). However, a gradient in vegetation sequences exists between France, Italy, and Greece, which illustrates the persistence of the present temperature and precipitation gradients between the three regions. In France and Italy, the vegetation history of temperate stages shares features in common with central European vegetation sequences (Iversen, 1958; Figure 3(b)). This includes a 'late-temperate' phase with abundant 'mountain' taxa (beech, fir, yew, spruce). In Greece, oak is always the dominant tree. There, even during glacial intervals, this tree remained present, sometimes abundant, showing that wood stands never totally disappeared. Tzedakis et al. (2002) showed a gradient between Ioannina and Tenaghi Philippon corresponding to different mesic situations.

Suborbital Forcing

During the 1990s, evidence accumulated which indicates short-term climatic changes during the last glacial interval, both from marine (Heinrich events, Bond events: Bond et al., 1997) and ice (Dansgaard-Oeschger events: Dansgaard et al., 1993) records. Cores from the Alboran sea show that these events are reflected in the western Mediterranean (Baudin et al., 2007; Combourieu-Nebout et al., 2002) and their consequences on the continent are now inferred from pollen records from France (Andrieu-Ponel et al., 2006; Wohlfarth et al., 2008), Italy (Allen et al., 2009), and Greece (Margari et al., 2009; Müller et al., 2011; Tzedakis et al., 2004a). On the continent, studies on lake-level changes also show that cyclic fluctuations during the

Figure 4 Comparison of south European terrestrial records and the marine oxygen isotope sequence. The solid lines represent the arboreal pollen (AP) curves minus *Pinus*; dotted lines the AP curves (including *Pinus*); and diamonds represent the control points used to align the chronologies. Modified from Tzedakis PC, Andrieu V, de Beaulieu J-L, et al. (1997) Comparison of terrestrial and marine records of changing climate of the last 500 000 years. *Earth and Planetary Science Letters* 150: 171–176.

Holocene correlated with changes in solar activity. Magny et al. (2007) have suggested similar (or independent) changes in the Holocene hydrological regime in the Mediterranean regions. However, comparable information for intervals prior to the last glacial remains lacking. An exception is an analysis of the changes in diatom populations during the last interglacial at Ribains, Velay, which suggests successive changes in seasonality during the last interglacial (Rioual et al., 2007). The challenge for the next decade may be to apply very high-resolution multi-disciplinary studies to the rare long Pleistocene series described here allowing better identification and understanding of sub-orbital climate variability in the Mediterranean regions.

Conclusion

The Mediterranean regions (mostly Greece and Italy) are unique in the world in terms of density of key Pleistocene pollen sequences. Moreover, the Velay sites provide a rare opportunity to connect middle Europe with southern Europe. The Mediterranean regions also constitute modern hot spots of biodiversity (Quézel and Médail, 2003). This conjunction provides a rare opportunity to put a long-term, paleoecological perspective on present-day ecology (Rull and Vegas-Vilarrubia, 2011), in order to address questions of biodiversity conservation (Samways et al., 2006; cf. Hampe and Pétit, 2005) in the context of global warming and increased human pressure.

Introduction

Pollen records from a variety of settings provide evidence of large-scale changes in vegetation and climate during the late Pleistocene (ca. 130 to 10 ka) in Western North America (WNA). This is the interval from the beginning of the last interglacial (MIS 5e) to the beginning of the current interglacial (the Holocene (MIS 1)). The late Pleistocene ended with the demise of the last of the megafauna (mammoths, mastodons, camels, llamas, horses, etc.) and was the last major episode of Earth history before humans transformed the globe. Our knowledge of the late Pleistocene in this region is uneven, and many more records are available for the last 20 ka of this interval than for the previous 100 kyr.

Pollen data from WNA illustrate several modes of vegetation change through the late Pleistocene, including shifts in the geographic and elevational ranges of plant taxa, and changes in the structure and composition of vegetation communities. The vegetation changes recorded in pollen records were caused primarily by global changes related to the radiation balance of the Earth and resulting shifts in climate zones. However, changes in the concentration of carbon dioxide in the atmosphere affected the water requirements of plants and may have caused them to be limited to wetter-than-present sites during portions of the late Pleistocene. Changes in the seasonal and geographic distributions of incoming solar radiation alone, independent of their effects on climatic circulation, may have also played a role in vegetation change, as may have changes in fire and other disturbance regimes (such as insect infestations). Ecological processes (e.g., succession), substrate requirements, and dispersal capabilities of individual taxa would have also influenced the pattern of vegetation change.

Environments of Western North America

WNA has a wide range of physiographic settings (Figure 1, Table 1) from the Great Plains on the eastern margin, through a broad region of high mountains and plateaus interspersed with valleys and plains, to the shores of the Pacific Ocean on the west. Winter temperatures are mild in the southwest and Mexico and along the Pacific Coast (Figure 2, upper left) while cold winters occur on the northern Great Plains and in the northern Rocky Mountains. Summers are hot in the southwest, in the Central Valley of California, and on the Great Plains (Figure 2, upper right). Although much of interior WNA is arid (due in large part to the rain shadows of the Sierra Nevada, Cascade, and other major mountain ranges), there are moist environments in the Pacific Northwest, northern Rocky Mountains, the high mountains of the central Rockies, and in the high Sierra Nevada mountains of eastern California (Figure 2, lower right; these are the regions with the most late Quaternary pollen records). Winter precipitation is dominant along the Pacific Coast, northern Idaho, and western Montana.

Summer rainfall prevails in northern Mexico, the eastern part of the southwest, parts of the Colorado Plateau, the southern Rocky Mountains, and the Great Plains. The regions between the pronounced areas of winter and summer precipitation have mixed regimes with varying ratios of warm-season to cool-season precipitation. Extremely dry summers occur today in central and southern California.

The present-day pattern of vegetation types follows the climatic gradients described above, and examples of the range of western vegetation are shown in Figures 3 and 4 (see Table 2 for a list of common and scientific names). Dense conifer-dominated forests occur in the wet environments of the Pacific Northwest and in northern California (Figure 3a). More open conifer-dominated forests occur in the high mountains of the interior (Figure 4a), frequently grading into a woodland where scattered trees are embedded in a matrix of shrubs (Figures 3b, 4c, and 4d). Alder and other hardwoods are present in the forests of the Pacific Northwest, while aspen, another hardwood, is a common plant in high mountains across WNA. Oak woodlands or scrub occur in California west of the crest of the Sierra Nevada (Figure 3c), in the southwest, and in the southern portions of the Colorado Plateau and Rocky Mountains. The intermountain valleys of the Great Basin and Colorado Plateau host shrublands dominated by sagebrush and other small-stature plants that are tolerant of aridity and heat (Figure 3d), and treeless tundra occurs in some of the highest mountains (Figure 4c). Grasslands occur on the Great Plains, in portions of the southwest and coastal California, in the central valley of California, and in eastern Washington.

Aspects of Quaternary Palynology in WNA

Fossil pollen records have been obtained in WNA and the surrounding region from a variety of water bodies, including the Pacific Ocean, large lakes in tectonic basins, small lakes and ponds (frequently in glaciated terrain), and wetland and mire deposits. The depositional setting influences the size of the area that is being recorded in the pollen data, with marine records representing broad areas whose rivers empty in the ocean near the pollen site. Large lakes with inflowing rivers may also receive pollen from a broad swath of vegetation spanning a large range of elevational and geographic settings. Pollen records from small lakes and mires usually reflect a much more local vegetation signal.

A relatively small number of wind-pollinated pollen taxa dominate most WNA pollen records. Unfortunately, some of the most prolific pollen producers represent a large number of species that grow under a broad range of environmental conditions. For example, many species of pine occur in woodlands and forests across the region under a variety of combinations of temperature and moisture conditions (Figure 5), but these different species generally cannot be differentiated based

Figure 1 The left panel is a shaded relief map of the physiography of western North America. The numbered circles on this map show the location of sites discussed in the text (the site names are shown in the upper right panel). The lower right panel shows the latitudinal and elevational placement of the sites used in the Pacific and Interior Late Glacial transects. The vertical color bands in this panel provide a key to the elevations shown on the shaded relief map.

on their pollen. Juniper pollen also represents a large number of species from different environments, while spruce (Figure 5), fir, Douglas fir, and hemlock are limited to cool and/or moist climates. Oak lives under warm summers and mild winters, whereas sagebrush represents hot summers and dry conditions (Figure 5). The pollen of saltbush and related taxa provide evidence of hot and dry conditions. Many of the plants in tundra, grassland, and desert environments are insect-pollinated and release relatively small amounts of pollen. Such plants are frequently invisible in pollen records, even if they are abundant on the landscape. The pollen of pine and other windborne 'exotic' pollen taxa blown in from nearby communities frequently overwhelms the native pollen of these communities.

Late Pleistocene Pollen Records

There are many pollen records in WNA and it is not feasible to cover all of them in detail in this article. Instead, the emphasis

here is on some of the key modes of change, their apparent rapidity, and the interpreted causes of these changes. The pollen records discussed have differing spatial and temporal scales of resolution and differing levels of age control between and within records. Pollen records from Ocean Drilling Program (ODP) cores, such as that from ODP 893a from the Santa Barbara Basin (discussed below), can be dated through reference to the marine oxygen isotope stratigraphy of the host sediments. For terrestrial records, radiocarbon dating provides age control for the past 40 ka and volcanic ash stratigraphy (tephrochronology) provides additional chronological controls, especially in the Pacific Northwest and northern Rocky Mountains. Unfortunately, it is extremely difficult to obtain reliable age controls on lacustrine sediments that are older than the reach of radiocarbon dating (all ages discussed below are given in calendric time). Consequently, the following text will focus on the overall patterns of change and variability through the late Pleistocene, rather than on detailed correlations among these records or between these records

Figure 2 Aspects of the modern climate of western North America are shown in the right panels and the upper left panel. A sketch map of major geographic regions overlies the climate data in the upper left panel and the names of states and provinces are shown in the lower left panel.

and other chronologies of climate change. The following discussion is organized by time following the terminology of the marine isotope stages (see [Table 3](#)).

Marine Isotope Stage 5

Few WNA pollen records extend back through Marine Isotope Stage (MIS) 5 and here we examine the pattern and general timing of variability during this time in four of the most continuous pollen profiles. The record from ODP Site 893A ([Heusser, 2000](#)) in the Santa Barbara Basin provides a well-dated suite of some of the most dramatic changes seen in a broad source area in southern California. The transition from

the penultimate glaciation (MIS 6) into MIS 5 is registered by the rapid decline of juniper approximately 130 ka ([Figure 6](#)) followed by a succession of maxima of pine, then oak, and then sagebrush over the course of the last interglacial. Oak reached its highest levels in the record between 130 and 120 ka, presumably reflecting the warmest conditions. Two subsequent high periods of oak (MIS 5c and 5a) alternate with periods of juniper dominance (MIS 5d and 5b), which, coupled with the ages provided by the marine oxygen isotope stratigraphy, reflect the warm-cold-warm-cold-warm sequence seen in the marine record of MIS 5.

Owens Lake, now drained to feed the water needs of southern California, was located at the southern end of Owens

Figure 3 Examples of present-day vegetation in the states adjacent to the Pacific Ocean: (a) dense old-growth conifer forest in western Oregon; (b) juniper woodland in a sagebrush matrix in eastern Oregon; (c) oak woodland in southern California; (d) sagebrush shrubland in eastern Oregon. Photographs by R. Thompson.

Valley, on the east side of the Sierra Nevada (**Figure 6**). The interval of the pollen record from this site that is thought to cover the last interglacial (**Woolfenden, 2003**) is shown in **Figure 6**. Although the assigned ages are inexact, the Owens Lake record shows an apparently rapid transition from MIS 6 to MIS 5 environmental conditions approximately 130 ka, similar to the ODP 893A record from the other side of the Sierra Nevada. At Owens Lake, juniper declined rapidly at the end of the penultimate glacial interval (MIS 6), followed by the beginning of a steady rise in pine (an increasing trend that continued through MIS 5e) and then increases in mountain mahogany, sagebrush, and saltbush. Oak (not shown in **Figure 6** at Owens Lake) achieved higher pollen percentages during the last interglacial here than during the current interglacial, perhaps indicating wetter conditions.

At Clear Lake in northern California west of the Sierra Nevada, oak provides a strong signal in the pollen record (**Adam et al., 1988**) that is interpreted to be indicative of warm conditions, as in southern California (**Figure 7**). Here oak pollen is at its highest levels of the late Pleistocene immediately prior to ~120 ka, suggesting conditions warmer than those of the Holocene during the last interglacial. As with the record from ODP 893A, fluctuations in the pollen data appear to register the sequence of changes seen in the marine record through MIS 5 (although the age controls for the Clear Lake record are not sufficient to prove this point).

The pollen record from Carp Lake, Washington (**Whitlock et al., 2000**), located on the eastern flank of the Cascade Range,

begins with what appears to be the last interglacial (**Figure 7**). Some of the pollen taxa (including juniper and oak) represented in MIS 1 (the current interglacial) are present prior to ~120 ka in this record, and spruce is nearly absent. Spruce, an indicator of colder conditions at this site, is present after that and the relatively high levels of sagebrush and grass pollen suggest open and somewhat dry environments. There are no indicators of pronounced warmth until what appears to be MIS 5a at ca. 80 to 75 ka. The vegetation of this interval was like nothing else during the late Pleistocene — juniper, western hemlock, and oak (along with fir, western hemlock, and saltbush, which are not shown in **Figure 7**) were at high levels, and, unlike the MIS 1 portion of the record, pine and red alder were at low levels.

Marine Isotope Stages 4 and 3

Juniper and sagebrush increase ca. 70 ka in both the ODP 893A and Carp Lake records (**Figures 6 and 7**), indicating the arrival of colder and drier conditions. Oak increases after ~60 ka in the Clear Lake record, but remains well below the levels seen in MIS 5 and MIS 1, suggesting sustained cool conditions through MIS 3 at this site. Oak is absent outside of MIS 5 and MIS 1 in the ODP893A pollen record.

At Carp Lake the onset of cooler and drier conditions nearly 70 ka is marked by decline in oak and juniper and increase in pine and sagebrush (**Figure 7**). Although conditions at this site were more 'glacial' during MIS 4 than during MIS 5 and MIS 3,

it was not as cold and dry as during MIS 2, when sagebrush and grass dominate the Carp Lake record. Pine declined after 60 ka and sagebrush and grass increased. This was the beginning of a long and oscillatory slide toward the glacial conditions

Table 2 Common and scientific names for pollen taxa and plants mentioned in the text

<i>Conifers</i>	
Douglas fir	<i>Pseudotsuga menziesii</i>
Fir	<i>Abies</i>
Hemlock	<i>Tsuga</i> (mountain hemlock is <i>T. mertensiana</i> , western hemlock is <i>T. heterophylla</i>)
Juniper	<i>Juniperus</i> (the pollen type as used here may include other genera in the Cupressaceae and related families)
Pine	<i>Pinus</i> (pinyon pine, as used here, includes <i>P. edulis</i> and <i>P. monophylla</i> ; ponderosa pine is <i>P. ponderosa</i>)
Spruce	<i>Picea</i> (sitka spruce is <i>P. sitchensis</i>)
<i>Hardwood trees</i>	
Alder	<i>Alnus</i> (red alder is <i>A. rubra</i>)
Aspen	<i>Populus tremuloides</i>
Birch	<i>Betula</i>
Mountain mahogany	<i>Cercocarpus</i>
Oak	<i>Quercus</i>
<i>Shrubs and herbs</i>	
Grass	Poaceae
Sagebrush	<i>Artemisia</i> section <i>tridentatae</i> (this includes <i>A. tridentata</i> (Figure 5) and related dry-adapted species)
Saltbush	Chenopodiaceae and <i>Amaranthus</i>

of MIS 2, although a marked short-lived reversal of the trend is seen in the increase in pine and decrease in sagebrush and grass ca. 40 ka.

The pollen record from Humptulips Mire in western Washington (Heusser et al., 1999) apparently began during MIS 4 (Figure 7). The levels of spruce and grass pollen during this interval suggest cold and dry conditions, perhaps exceeding those of MIS 2 at this site. The subsequent increase in pine and western hemlock after ~60 ka suggests warmer conditions, although the high levels of pine and the low levels of alder suggest cooler and drier conditions than during MIS 1.

Marine Isotope Stage 2

There are substantially more data available for MIS 2 than for earlier times, although many montane sites were occupied by ice at the LGM (upper left of Figure 8). For the California and Washington State records discussed above, the LGM is generally the interval of greatest dominance of pollen taxa indicative of cold and/or dry conditions. In the Clear Lake record, oak is at its lowest levels (Figure 7), and the Carp Lake record has its highest values for spruce, sagebrush, and grass (coupled with the lowest values for pine). At Carp Lake, the end of MIS 2 is marked by a sharp transition as spruce and sagebrush essentially disappear and pine, western hemlock, oak, and red alder rise. The Humptulips Mire record also shows a marked change at this time, with decreases in pine, grass, and mountain hemlock and increases in western hemlock, alder, and spruce (presumably here the maritime Sitka spruce rather than the cold-adapted species of the interior).

Figure 5 The present-day geographic and climatic distributions in western North America of four taxa that are well-represented in late Pleistocene pollen in the region (Little, 1971, 1976). The heights of the bars in the histograms indicate the percentage of the total number of occurrences of the taxon that falls within the climatic range indicated on the horizontal axis (Thompson et al., 1999a,b).

Table 3 The approximate ages (from [Martinson et al., 1987](#)) and global environments for the marine isotope stages (MIS)

MIS 5:	130 000 to 75 000 yr BP, the marine isotope stratigraphy has large amplitude swings within this interval with warm substages (from oldest to youngest) 5e, 5c, and 5a separated by relatively cool conditions during substages 5d and 5b. MIS 5e is often viewed as the 'last interglacial.'
MIS 4:	75 000 to 60 000 yr BP, the initial period of continental-scale glaciation, which was of a smaller magnitude than the Last Glacial Maximum (LGM).
MIS 3:	60 000 to 25 000 yr BP, a long interval of conditions intermediate between the warmth of the interglacials and the cold of the LGM.
MIS 2:	25 000 to 10 000 yr BP, the interval encompassing the LGM (~21 000 yr BP) and the transition to the current interglacial.
MIS 1:	10 000 yr BP to the present: The current interglacial, the Holocene.

Biomes of the LGM

The greater number of sites available for the LGM provides the basis for synoptic-scale reconstruction of past biomes and comparisons with their modern distributions. The lower portion of [Figure 8](#) shows the modern geographic distributions (compiled from the data presented by [Küchler \(1964\)](#)) and climatic tolerances of three biomes that cover most of WNA, and the upper right panel shows the distribution of these biomes as estimated from modern pollen data ([Thompson and Anderson, 2000](#)). The biomes presented here are forest (where trees dominate and there is relatively little open vegetation; examples shown in [Figures 3a](#) and [4a](#)), woodland (trees scattered with a matrix of shrubs and herbs; examples – [Figures 3b, 3c, 4b, and 4d](#)), and shrubland–grassland (trees are largely absent; example – [Figure 3d](#)).

In general, there is a good match between the two modern maps, although the pollen-based maps do have woodland

Figure 6 Marine isotope stage (MIS) 5 in the pollen record from ODP Site 893A and MIS 5e in the pollen record from Owens Lake, California ([Table 1](#)). These data were digitized from the published diagrams. For ODP Site 893A the age model was taken from the published diagram on pollen groups and applied here to the individual pollen taxa.

Figure 7 Records spanning all or much of the late Pleistocene from Clear Lake, California, Carp Lake, Washington, and Humptulips Mire, Washington (Table 1). These data were digitized from the published diagrams. For Clear Lake the ages were determined by taking the MIS boundaries plotted by Adam et al. (1988) and interpolating the ages of the samples between these boundaries.

farther north (this may be a mismatch between the two approaches, because pollen spectra receiving input from forest and shrubland–grassland would integrate them into a woodland). Conifer-dominated forests prevail in the Pacific Northwest and in the high elevations of the Sierra Nevada and Rocky Mountains. A few lower-elevational pollen records (yellow in Figure 8) show the presence of sagebrush- or grassland-dominated vegetation. Woodland (usually with pinyon pine, juniper, and/or oak short-stature trees) occurs in dry environments on the lower mountain slopes and plateaus of the interior, and shrubland–grassland occurs on the Great Plains, in the intermountain valleys, and in the central valley of California. Although the geographic ranges of the biomes intermingle and their climatic ranges overlap (Figure 8), in general, forest has the highest moisture levels combined with the lowest temperatures. Shrubland–grassland has lower moisture availability coupled with warm summers and winters as cold as those in forests. Woodland has intermediate moisture availability, with summers as warm as shrubland–grassland, but winters warmer than the other two biomes.

The biome reconstructions for the LGM (Figure 8, upper left panel) indicate that forest was restricted to the westernmost maritime portion of the Pacific Northwest. Across most of the rest of the landscape the vegetation was an open-conifer woodland, where subalpine conifers (in the north) or pygmy woodland conifers (to the south) lived in an open matrix with sagebrush, grass, and other steppe plants. Cold and dry climates are inferred for these latter areas, although the

physiological effects of low levels of atmospheric carbon dioxide may have restricted trees to wetter sites than today (see Van de Water et al. (1994) for evidence that trees in WNA had a higher density of stomata at the LGM than today, due to the lower levels of atmospheric carbon dioxide. The larger number of stomata would have released more water vapor from the trees, requiring them to use more water than they do under present-day conditions). Plant macrofossil records in the southwestern deserts (at lower latitudes and lower elevations than the pollen records) indicate conditions wetter and cooler than at present. The contrast between drier conditions to the north and wetter conditions to the south suggests that the westerlies were displaced southward at the LGM (Thompson et al., 1993).

Transition from glacial to interglacial conditions

Most of the Pleistocene pollen records in western North America begin after the LGM, due in part to the presence of glaciers in the high mountain basins where many of the records are located (Figure 8). These glaciers began to retreat by 17 ka, and there are many pollen profiles that record the transition from glacial to interglacial conditions in WNA, a transition that is expressed differently in different places and at different elevations. Figure 9 illustrates some of the changes seen across WNA during the transition from glacial to interglacial (Holocene) conditions between 17 and 9 ka along two north–south transects of pollen sites (Figure 1), one along the Pacific margin and the other in the more dry and continental interior. As discussed below, there is considerable variability imposed

Figure 8 The upper panels illustrate the biomes of western North America at the Last Glacial Maximum (LGM) inferred from pollen data compared with those inferred for today (Thompson and Anderson, 2000). Glaciers and lakes on the LGM panel from Dyke et al. (2003). The lower panels illustrate the present geographic (Küchler, 1964) and climatic distributions of modern vegetation assemblages that approximate the biomes identified in the pollen data.

on the long-term trend at individual sites. Some of this variability may be tied to the Younger Dryas (e.g., Reasoner and Jodry (2000)) or other North Atlantic fluctuations, although the age controls available for most sites are not sufficient to make definitive correlations with distant events.

Pacific transect. This transect includes the wettest environments in present-day WNA (Figure 2), and elevations along it range from near-sea level in the north to high elevations in the Sierra Nevada to the south (Figure 1). At the three northern sites glacial-age pine forests are replaced by forests dominated

Figure 9 Two latitudinal transects of pollen sites illustrating the nature and timing of the transition from Pleistocene to Holocene vegetation in western North America (Table 1). The data are from the North American Pollen Database (NAPD, see Table 1 for citations and site information) and the age assignments are based on the NAPD age models. Calendric ages are shown on top, and radiocarbon years are plotted on the bottom (scaled by radiocarbon years indicated in NAPD files). Vertical dashed lines indicate 1000 year intervals in calendric time. The pollen taxa shown in this figure include pine, spruce, and sagebrush (illustrated in Figure 5), and alder. For the Pacific transect, the 'other conifers' category includes fir, Douglas fir, juniper, and hemlock. The 'other conifers' group is less important for the interior transect and is included in the 'other trees and shrubs' category. Sagebrush is relatively unimportant for the Pacific transect and is included in the 'grass and other herbs' category. Taxa shown in yellow and orange indicate open environments, those in green and blue are forest types.

by other conifers (including initially spruce, and then Douglas fir and hemlock) and alder by 16 to 13 ka. At the fourth site, Davis Lake (WA), spruce was more important than at the sites to the north at the close of the glacial interval, and there were more pollen indicators of open vegetation. These glacial taxa declined between 17 and 14 ka, and by 13 ka were largely replaced by other conifers (fir, Douglas fir, juniper) and alder. The transition at the next site to the south, Battle Ground

Lake, is more complex than the previous sites, with more open vegetation throughout and more variability. The early part of the interval had sagebrush and grass as indicators of open conditions; by the end of this interval sagebrush was largely gone, grass diminished, and there was a new suite of taxa indicating open vegetation. A peak in 'other conifers' prior to 12 ka is a brief interval of overlap between a short-lived maximum in fir pollen and the initial rise of Douglas fir. At this site

some of the important trees of the Holocene, including hemlock, were not established until 9 ka. Forests were present during the glacial interval at the final site of this transect in the Pacific Northwest (Little Lake (OR)), although sagebrush and other indicators of open vegetation were present. Here spruce departed earlier than 15 ka and forests with alder, fir, and Douglas fir became established.

The two southerly sites on the Pacific transect are located in the high Sierra Nevada Range of eastern California. At Swamp Lake, the basal glacial-age pollen spectra indicate pine-dominated forests with some indicators of open vegetation (including sagebrush and grass). Pine dominance continues through the glacial–interglacial transition, although there are significant increases in alder, other conifers (especially juniper), and other trees and shrubs about 13 ka. The most southerly site (Exchequer Meadow) is a high-elevation meadow today and the early part of its record is dominated by sagebrush, grass, and other plants indicative of open vegetation. The representation of trees increases through the interval of interest, with juniper at high levels between 13 and 12 ka, followed by pine dominance with fir and oak.

Interior transect. This transect covers environments that are generally colder, drier, and higher than those along the Pacific transect. The modern forests along the transect have pine, spruce, Douglas fir, and fir as common elements. The widespread occurrence of sagebrush (Figure 5) reflects the dryness and open vegetation of the valleys in the Rocky Mountain region. The basal spectra of the three northern sites date to slightly younger than 14 ka, and the base of Lily Lake Fen (WY) dates to ~15 ka. The earliest recorded vegetation at these four sites is significantly more open than that of today, and the sagebrush, grass, juniper, and birch pollen characteristic of this early interval are replaced by pine-dominated forest by 12 to 10 ka. The next site to the south, Rapid Lake (WY), shows a similar transition at ca. 11 ka when sagebrush and grass decline as pine, spruce, fir, and saltbush rise.

The transition at Splains Lake, farther south in Colorado, was similar in composition and scope, but apparently occurred more gradually as pollen taxa indicative of open environments decline from 70% at 16 ka to less than 30% by 11 to 10 ka. Pine, spruce, and fir increased at this site after 12 ka. At Molas Lake in southwestern Colorado, only the pollen spectra older than 16 ka have significant representations of open vegetation indicators. A forest with pine and spruce is dominant after that time, although grass and herbs increase after 12 ka. The southernmost site, Potato Lake (AZ), has a glacial-age spruce–pine forest with sagebrush that was gradually replaced by a pine–grass complex (with spruce disappearing around 12 ka). The trend at this site is similar to that seen in the macrofossil records from the southwest deserts, and, unlike the pollen records discussed above, forest here gave way to increasingly open and dry environments through the glacial–interglacial transition.

Summary

During the late Pleistocene in WNA, forests were at their greatest extents during the warm climate intervals in MIS 5 and MIS 1, perhaps due to both the climate and the relative abundance of

carbon dioxide in the atmosphere. During these times, oak and other warmth-requiring plants spread northward and to higher elevations. During the coldest climates of the late Pleistocene (MIS 4 and MIS 2) these plants retracted downslope and to the south, forests diminished, and plants adapted to cold and dry conditions spread into areas that today support moist forest environments. Vegetation apparently changed rapidly to many of the climatic variations described above, and the amplitude and rate varied among geographic and elevational settings.

Introduction

During the last glacial–interglacial transition, the orbitally induced increase in solar radiation during summer had pronounced effects on tropical monsoon activity. Enhanced thermal contrast between land and sea and the related land–sea pressure gradient were responsible for strong inflow of moist maritime surface winds toward the African continent. Enhanced monsoon fluxes over tropical Africa led to the establishment of numerous lakes and the wide development of tropical plant communities throughout the African tropics during the Holocene (e.g., [Hoelzmann et al., 1998](#); [Lézine et al., 2011](#); [Watrin et al., 2009](#)). The greening of the Saharan desert supported abundant faunas and led to the early development of grazing and agriculture ([Petit-Maire, 1999](#)).

The shift from dry and cool to humid and warm climate conditions in tropical Africa has been studied by numerous authors (e.g., [de Menocal et al., 2000](#); [Gasse, 2000](#); [Kröpelin et al., 2008](#); [Lézine et al., 2005](#)) with the aim of investigating the timing and structure of the last glacial–interglacial transition in the African tropics. The role of the North Atlantic Ocean circulation has also been proposed to explain the millennial-scale climate oscillations that punctuated this interval. In addition, paleoclimatic models connecting environmental changes with variations in the Earth's orbit ([Kutzbach and Street-Perrott, 1985](#)) or investigating atmosphere–vegetation feedback in the climate system ([Broström et al., 1998](#)) have been used to study the mechanisms of climate variability.

Environmental reconstruction of tropical Africa from pollen data is severely limited by the incompleteness of the record, owing primarily to major discontinuities in lacustrine sediments

preserved in a predominantly arid climate. Long and complete pollen records from the interval lasting from the last glaciation to the present are extremely rare (e.g., Sacred Lake ([Coetzee, 1967](#)); Barombi M'Bo ([Maley, 1991](#)); Lake Bambili ([Assi-Kaudhis et al., 2008](#))). In this context, marine sedimentary sequences offer the possibility of providing additional evidence of environmental and climate changes on the nearby continent. In this review, I use pollen data from both continental and marine sedimentary sequences ([Figure 1](#) and [Table 1](#)) to discuss short- and long-term climate changes that occurred in tropical Africa during the last glacial–interglacial transition and the Holocene and the related variations in plant distribution.

Evidence of Past Atmospheric Circulation: Influx Values in Marine Pollen Sequences off West Africa

Core KS84068 (4°28'N, 4°11'W) recovered in the Gulf of Guinea off the Ivory Coast and core A180-48 (15°19'N, 18°06'W) recovered off Senegal, in zones out of any direct influence of river discharges, provide detailed evidence for important changes in the strength of the two main air fluxes that drive the West African climate ([Lézine, 1998](#)). These are the continental trade wind of NE–SW direction, which crosses the dry and hot Saharan desert, and the Atlantic monsoon, which blows in the opposite direction and carries humid air masses to the continent in summer. The confluence of these two air masses (the Inter-Tropical Convergence Zone) moves from roughly 4°N in January to 20–25°N in July ([Figure 2](#)). Continent–ocean exchanges are deduced from the variations in pollen influx (number of grains per cm² per year; [Figure 3](#)). Core KS8403, with a sediment accumulation rate

ranging from 4 to 10 cm per 1000 years, provides an exceptional record for the time interval of 19 000–3000 cal yr BP. Two well-marked peaks of pollen influx are recorded for the onset of deglaciation (2000 grains per cm² per year) and the Younger Dryas interval (3000 grains per cm² per year) at levels characterized by the occurrence of pollen grains from the Saharan desert (such as *Artemisia* (Sage) and *Ephedra* (Mormon tea)) and high concentrations of eolian dust. These testify to the enhanced trade wind circulation during dry events. Conversely, early Holocene levels centred ca. 9500 cal yr BP are characterized by minimum values of pollen influx (770 grains per cm² per year) as a response of SW–NE dominant wind fluxes during the early Holocene humid maximum. Core A180-48 confirms the importance of pollen influx values during the Younger Dryas event with a maximum of 9600 grains per cm² per year. The base of the core is poorly dated, which precludes any reliable record before 15 000 cal yr BP.

Reinforced eolian activity of NE direction over the eastern tropical Atlantic corresponds to phases of severe dryness on the nearby continent, leading to the lowering of lake and water table levels (Figure 3; Gasse, 2000). The low values of pollen influx recorded before the Younger Dryas (at a time interval corresponding to the Bölling/Alleröd pollen zones of Northern Hemisphere) and the early Holocene correspond to the reversal of dominant wind fluxes and enhanced monsoon circulation responsible for high lake levels throughout North Africa (Gasse, 2000).

Figure 1 Location map of pollen sites mentioned in the text. Modern definitions of vegetation according to [White \(1983\)](#) with: I, Guineo–Congolian forests; II, Zambezian dry forests and woodlands (including Miombo); III, Sudanian dry forests and woodlands; IV, Somalia–Masaï wooded grasslands; X, Guineo–Congolian/Zambezian transition zone; XI, Guineo–Congolian/Sudanian transition zone; XII, Lake Victoria mosaic; XIII, Zanzibar–Inhambane mosaic; XVI, Sahelian wooded grasslands; XVII, Saharan desert. In black: Afro-montane forests and grasslands.

Figure 2 Modern surface wind fields for Africa for boreal winter (January) and summer (August). During boreal summer, heating over land surface allows moist maritime air from the equatorial Atlantic to penetrate into western and central subtropical Africa. Strong southwesterly winds associated with the summer Asian monsoon develop in East Africa, while westerly airstreams of the Atlantic monsoon penetrate eastward and reach the Eastern highlands. Regional atmospheric circulation reverses during boreal winter, and dry northeast winds blow over subtropical Africa.

Pollen records of the Younger Dryas dry event on the African continent are extremely rare because most of the lakes dried up at this time. It is, however, probable that the interruption of the forest advance at Lake Bosumtwi ($6^{\circ}32'N$, $1^{\circ}25'W$) between 15 000 and 10 600 cal yr ([Maley, 1991](#)) and Lake Albert ($1^{\circ}50'N$, $31^{\circ}10'E$) between 13 300 and 11 200 cal yr BP ([Beuning et al., 1997](#)), and the well-identified phase of extension of halophytic herbaceous vegetation at Lake Magadi

around 12 900 cal yr BP ([El Moutaki, 1994](#)) correspond to this event. In southeast Africa, however, rather different climate conditions prevailed as shown, for instance, at Lake Masoko ($9^{\circ}20'S$, $33^{\circ}45'E$) ([Vincens et al., 2007](#)) with high rainfall prior to 11 700 cal yr BP (including the Younger Dryas event) allowing a semideciduous forest (forest with some deciduous and some evergreen trees) to expand. A dramatic change in vegetation composition at 11 700 cal yr BP led to the wide expansion

Figure 3 Pollen evidence for dry climate phases in western tropical Africa. Two curves at the left show the variations in trade wind intensity inferred from two pollen influx records (A18048 and KS84063) from the eastern Atlantic Ocean at 15° N and 4° N (Lézine, 1998). Peaks in pollen influx correspond to dry phases recorded by episodes of low lake level (in records from Lake Bosumtwi, Bahr-el-Ghasal, and the Chad basin) on the nearby continent. Two main dry phases are recorded at the onset of the deglaciation and the 'Younger Dryas' event, whereas two more discrete phases of trade wind intensity are dated from ca. 8000 to 4000 cal yr BP. Reproduced from Gasse F (2000) Hydrological changes in the African tropics since the Last Glacial Maximum. *Quaternary Science Reviews* 19: 189–211.

Figure 4 The African Humid Period as recorded around 21° N (ODP site 568 terrigenous record) from de Menocal et al. (2000) (left) and around 3° N (Core KW31 algae record) from Lézine et al. (2005) (right). The figure shows that the onset of deglaciation was very unstable, characterized by phases of intense flowing (peaks in *Pediastrum* curve) and interruption of river discharges to the ocean. Peaks of *Botryococcus* record phases of dominant surficial runoff in a poorly vegetated environment. At the end of the African Humid Period, the record of the onset of modern conditions was abrupt near the northern tropic and more progressive near the equator, occurring in three steps at 7000, 5500, and 3500 cal yr BP. (*G. Ruber* = *Globigerinoides ruber*, a foraminiferan sensitive to salinity changes).

of open and dry plant communities of Zambezi affinity. This change is interpreted as reflecting not only a decrease in annual rainfall but also a change in rainfall distribution with a dry season changing from 3–4 months prior to 11 700 cal yr BP to 5–6 months after.

Evidence of Past Rainfall Variations: Fresh-Water Algae Record in Marine Pollen Sequences off West Africa

Owing to its location off the mouth of the Niger River, the palynological content of core KW31 (3°31'1"N, 05°34'1"E;

Lézine et al., 2005) is thought primarily to reflect variations in fresh water flowing to the ocean. In this core, pollen grains are associated with an abundant and highly diverse fresh-water algal flora, including *Pediastrum* (a colonial green alga), which has been used to characterize the successive hydrological phases of the African Humid Period. As depicted by the *Pediastrum* curve, strong fresh-water discharges started ca. 14 500 cal yr BP, at the time of the Bölling/Allerød interval, with a peak dated from 13 650 cal yr BP (KW31) (Figure 4) and culminated during the Holocene. The whole interval, which corresponds to the increase in summer radiation at the last glacial–interglacial transition, was climatically very unstable, characterized by an

Figure 5 West African vegetation changes at the last glacial-interglacial transition. This figure shows the variations in pollen influx recorded in core KW31 recovered off the mouth of the Niger River in the Gulf of Guinea and the occurrence of tropical trees in the nearby continent from about 5° S to 25° N. Dashed line indicates the northward progression of tropical trees, which started about 14 500 cal yr BP near the equator and reached the northern tropic about 9 000–8 500 cal yr BP. Reproduced from [Lézine A-M and Cazet J-P \(2005\)](#) High resolution pollen record from core KW31, Gulf of Guinea, documents the history of the lowland forests of West Equatorial Africa since 40,000 years. *Quaternary Research* 64: 432–443.

alternation of phases of intense flowing and abrupt interruption of the fresh water supply to the ocean. Two main short 'dry' events are successively recorded between 13 400 and 12 100 cal yr BP, then around 11 400–11 200 cal yr BP, that closely correlate with events recorded in the GRIP ice record ([Blunier et al., 1997](#)) or more widely throughout the globe (the Younger Dryas interval). During these intervals, the low values of *Pediastrum* and the correlative increasing values of *Botryococcus* or *Staurastrum* (both green algae) indicate that river flow was considerably reduced and replaced by surficial runoff. At the end of the African Humid Period, a shift to drier conditions developed progressively from 7 100 cal yr BP, and the modern Niger River outflow was definitively established at 3 500 cal yr BP. The terrigenous (eolian) record at ODP site 658 ([de Menocal et al., 2000](#)) strongly contrasts with the KW31 algae record by showing that, near the Tropic of Cancer, the onset and the end of the African Humid Period occurred very abruptly, within decades to centuries around 5 500 cal yr BP.

Vegetation Response to Enhanced Monsoon Circulation and Global Warming at the Onset of the Last Deglaciation

Extension of Tropical Forest Ecosystems in West Africa and the Greening of the Saharan Desert

KW31 pollen content confirms previous studies carried out at Bosumtwi (Ghana) and, to a lesser extent, at Barombi M'Bo (Cameroon), according to which forests were strongly reduced in area during the last glacial stage. Increased monsoon rains since 15 000 cal yr BP led to the wide expansion of forests throughout north tropical Africa. However, comparisons between ocean and continent pollen records ([Figure 5](#)) point to a noticeable time lag between the strengthening of monsoon fluxes in the Gulf of Guinea and the vegetation response on the nearby continent. The continental pollen records suggest that forests expanded in the Cameroon midlands at 11 600 cal

Figure 6 Diogo 2 (Senegal) summary pollen diagram showing percentages of the main pollen taxa. To the left, the main trees, to the right, the main herbaceous plants, and, in the middle, a synthetic diagram showing the variations of the main groups of taxa: trees, undifferentiated (trees, shrubs, herbs, or lianas), ferns, and upland and aquatic herbs. Percentages are calculated using a sum including all the determinable pollen and fern spores. (Data from the African Pollen Database). Reproduced from [Lézine A-M \(1998\)](#) Pollen records of past climate changes in West Africa since the Last Glacial Maximum. In: Issar A and Brown N (eds.) *Water, Environment and Society in Time of Climatic Change*, pp. 295–317. Dordrecht: Kluwer Academic Publishers.

yr BP, that is, more than 3 millennia after the start of the Niger River flow to the ocean and the extension of moist forests in southern Congo. Moist forests were established in the Sudanian zone at 11000 cal yr BP, then the western Guineo-Congolian forest domain, and the Sahel one millennium later, between 10500 and 9500 cal yr BP ([Figure 6](#)). Lastly, tropical trees entered the Saharan desert around 9500–9300 cal yr BP ([Figure 7](#)).

The Diogo interdunal depression ([Figure 6](#)) lies inland from the Atlantic coastal strand of Senegal north of the Cap Vert Peninsula at about 15°N ([Lézine, 1989](#)). It yielded a continuous pollen record for the interval lasting from 11500 cal yr BP to the present. From the beginning of the sequence to 10300 cal yr BP, the regional vegetation was dominated by herbaceous plant types, mainly Poaceae (grass), suggesting the prevalence of scrub- and grasslands (zone 1). The abrupt increase in tree pollen percentages by 10300 cal yr BP records the sudden expansion of tropical gallery forests since most of the taxa are of Guineo-Congolian and Sudanian phytogeographical affinity (*Celtis* (hackberry), *Tetracera alnifolia*, *Elaeis guineensis* (African oil palm), *Alchornea*, *Macaranga*, Moraceae (fig family), etc.) (zone 2a). Around 7500 cal yr BP, the most characteristic Guineo-Congolian forest trees disappeared and swamp forests dominated by *Syzygium* developed suggesting climate deterioration (zone 2b). From 3500 to 2500 cal yr BP, Guineo-Congolian trees (*Elaeis guineensis*, *Uapaca*, *Anthostema*

senegalense) went through a second phase of expansion recording increasing moisture conditions in the Niayes area (zone 2c). This wet phase abruptly ended at 2500 cal yr BP, leading to a rapid degradation of the forests and the setting of modern environmental conditions (zone 3).

The Oyo depression lies in one of the most arid area of NW Sudan at roughly 19°N. The pollen diagram ([Figure 7](#)) shows that tropical tree species of Sudano-Sahelian affinity (*Piliostigma*, *Grewia tenax*, *Lannea*, *Celtis*) occurred in the immediate surroundings of the lake from 9500 cal yr BP to the mid-Holocene and did not disappear before 5000 cal yr BP ([Ritchie, 1994](#)). At this date, the regional climate became drier and the vegetation was dominated by Sahelian *Acacia* (thorn tree) scrub- or grasslands. Desert conditions were established definitively around 5000 yr BP and the Oyo basin completely dried out.

From west to east, all the pollen diagrams from the southern fringe of the modern Saharan desert record a similar presence of pollen types from tropical-Sudanese (Sudano-Guinean) and Sahelian phytogeographical zones. More than 50 tropical tree pollen types have been enumerated from 11 pollen sites from 16°15' to 25°45'N ([Table 2](#)), which testify to the presence of the parent trees in the immediate surroundings of the lakes. However, their very low percentages indicate that tropical trees were scarce and most probably primarily restricted to gallery forests along freshwater bodies. Pollen

Figure 7 Oyo (Sudan) summary pollen diagram. See [Figure 6](#) for details. (Data from the African Pollen Database). Reproduced from [Ritchie JC \(1994\)](#) Holocene pollen spectra from Oyo, northwestern Sudan: Problems of interpretation in a hyperarid environment. *The Holocene* 4(1): 9–15.

spectra remained dominated by pollen from herbaceous plant types (Poaceae, Amaranthaceae/Chenopodiaceae (amaranth/goosefoot families)), while pollen grains from xerophytic plant communities that characterize the modern desert were also present (e.g., *Ziziphus mauritiana*-type, *Salvadora persica*-type, *Tamarix* (tamarisk), *Ephedra*, *Artemisia*). This indicates that plants that nowadays occupy distinct vegetation (eco-climatic) zones in North Tropical Africa (tropical-Sudanian, tropical-Saharan, Saharan desert) were found together, representing a complex, no-analogue situation ([Figure 8](#); [Watrin et al., 2009](#)). During the early to mid-Holocene, the vegetation of the Saharan desert considerably increased its diversity while accommodating humid adapted species from tropical forests and wooded grasslands.

The Retreat of ‘Cool’ Species from the Lowland Guineo–Congolian Forests

Pollen records of the last glacial stage document the general descent of upper treeline by 1000–1700 m on the tropical mountains. Ericaceous (heath) scrubs and grasslands widely expanded in the surroundings of most of the lakes or peat bogs of East Africa, in response to cool and dry climate conditions ([Farrera et al., 1999](#)) and/or substantial lowering of CO₂ concentration ([Figure 9](#); [Street-Perrott et al., 1997](#); [Jolly and Haxeltine, 1997](#); [Wu et al., 2007](#)). Forests were considerably

reduced in area in the highlands, whereas some of their components entered the lowland Guineo–Congolian forest as recorded in pollen records at lakes Bosumtwi (Ghana) and Barombi M’Bo (Cameroon).

The pollen diagram from Bois de Bilanko, Congo (3° 31’S, 15° 1’E; 600 m alt; [Figure 10](#)), shows that montane plant species (*Olea capensis* (black ironwood), *Podocarpus* spp. and *Ilex mitis* (African holly)) persisted in the lowlands of southern Congo until slightly after 12 000 cal yr BP. Related pollen percentages reach significant values of 5%, 35%, and 10%, respectively, attesting to the presence of the corresponding trees near the core site in association with elements of lowland tropical forests. Then the progressive climate warming led to the disappearance of these heat-intolerant plant species from the lowlands. The latest occurrence of *Podocarpus* and *Olea* (olive) pollen grains in the Atlantic central African pollen sites is recorded at Njupi, Cameroon, around 2500 cal yr BP.

The northern boundary of the Guineo–Congolian forest domain reveals a surprising phase of *Olea capensis* (East African olive) expansion at the beginning of the Holocene, ca. 10 500 cal yr BP. Noticeable pollen percentages of *Olea* are recorded at several lowland sites from 3° to 10°N: up to about 20% at Bosumtwi at 10 000 cal yr BP, that is, more than twice as much as the percentages reached during the glacial times; 14% at Tilla where the *Olea* phase spans from 10 630 to 9800 cal yr BP; 3% at Tjeri from 9500 to 8100 cal yr BP. Because pollen

Figure 8 Latitudinal distribution of selected pollen taxa from 14 000 to 1 000 yr BP in western tropical Africa. Curves show probability densities calculated from pollen percentages (normalized for each taxon and varying from 0 to 1). This figure shows that, during the Holocene, plants that belong to distinct vegetation zones today occupied a common area at the time of the ‘green Sahara,’ about 9000 years BP. Reproduced from [Watrin J, Lézine A-M, and Hély C \(2009\) Plant migration and ecosystems at the time of the ‘green Sahara’. *CR Geosciences* 341: 656–670.](#)

percentages more than 10% are thought to indicate the presence of the parent plants (Coetzee, 1967), it is clear that *Olea* expanded in the immediate surroundings of Bosumtwi and Tilla and was also probably present in the southern Lake Chad basin. The *Olea* phase predates the expansion of the other pioneer forest types (such as *Alchornea*, *Macaranga*). Its significance (both climatic and biologic) is not yet fully understood. It is probable that *Olea capensis*, which is known to be a forest edge colonizing species (Kendall, 1969), benefited from the absence of competition from other trees and was able to extend its range during early postglacial times. It disappeared when the increase in temperature and rainfall was sufficient to permit the expansion of more heat- and moisture-tolerant pioneer trees.

The Upward Forests Expansion in Eastern Africa

Numerous pollen diagrams document the upward forest expansion in East Africa (Figure 9). However, most of the data comes from sedimentary sequences, which are discontinuous or poorly dated, thereby obviating any reliable reconstruction of vegetation dynamics at a regional scale. In addition, pollen sites have been obtained from a wide altitudinal gradient in various types of environments from lowland wooded grasslands to upland forests or alpine scrublands, from the edge of

the Guineo–Congolian forest massif at the west to the eastern side of the Rift valley. I present here three examples from continuous pollen records from the lowland dry forests surrounding Lake Tanganyika, the montane forest belt in Mount Kenya, and the upper limit of the forest in the Ruwenzori massif, in order to illustrate the postglacial forest history of East Africa.

Lake Tanganyika lies within the Zambezian Miombo woodland at 773 m altitude (Figure 11). The catchment basin extends over 231 000 km² to more than 3000 m altitude and is occupied by a wide range of vegetation associations including lowland dry woodlands and wooded grasslands, the so-called ‘Miombo,’ mainly composed of Caesalpiniaceae plant types (*Brachystegia*, *Julbernardia*, and *Isobertinia*), upland rainforests, and alpine scrub- and grasslands. Several cores from the northern (Sd14) and southern (MPU12) sub-basins were studied by Vincens (1989, 1991) and yielded detailed records of the last glacial–interglacial transition and the Holocene. Ericaceous plant communities, which widely expanded in the surroundings of the lake during the last glacial within degraded Miombo formations (zone 1), started to decrease by 17 600 cal yr BP and nearly disappeared from the lowlands by 14 000 cal yr BP in the southern basin and 12 000 cal yr BP in the northern basin (zone 2). During the interval from 17 600 to 12 000 cal yr BP, montane forest elements (*Olea* and *Myrica* (bayberry))

Figure 9 East African vegetation changes at the last glacial–interglacial transition. Top: the modern distribution of the main vegetation belts in the East African mountains (reproduced from [Hedberg 1951](#)) Vegetation belts of the East African Mountains. *Svensk Botanisk Tidskrift* 45(1): 141–202). Bottom: pollen sites plotted according to elevation from 750 (Lake Albert) to 4040 m (Kimilili). Forests disappeared from the African uplands during the last glacial interval except for a short phase centered around 35 000 cal yr BP. Trees started to expand from 15 000 cal yr BP.

Figure 10 Occurrence of tree pollen types from 'cold' plant species in West African diagrams. Barombi M'Bo and Bosumtwi data are redrawn from Maley (1991). The other pollen data are from the African Pollen Database.

expanded in the nearby mountainous areas in response to the progressive climate amelioration. Miombo plant types, mainly *Brachystegia* and *Uapaca kirkiana*-type, started to spread during the same interval, while the Miombo flora greatly diversified after 12 000 cal yr BP and included more wet tolerant plant types with Guineo–Congolian affinity, such as *Tetrorchidium*, *Holoptelea grandis*, and *Pycnanthus angolensis* (zone 3). This clearly indicates the onset of moist climate conditions near Lake Tanganyika. The late Holocene interval is poorly documented at Lake Tanganyika. However, the uppermost levels of core Sd14 suggest the degradation of lowland vegetation types during the last two millennia and the establishment of *Podocarpus* populations in the uplands.

Sacred Lake is a crater lake situated at 2400 m altitude (Figure 12). It yielded one of the most famous and longer pollen sequences from East Africa, spanning from about 38 500 cal yr BP to the present (Coetzee, 1967). The lake is situated in the montane rainforest zone, in the humid forest composed of *Pygeum africanum*, *Polyscias kikuyensis*, *Macaranga kilimandscharika*, *Neoboutonia macrocalyx*, *Apodytes dimidiata*, *Cassipourea malosana*, *Afrocrania volkensii*, *Syzygium guineense*, and so on. From the base to 12 200 cal yr BP, the pollen assemblages are dominated by herbaceous types, mainly Poaceae and *Artemisia*, which attest to dry and cold conditions during the glacial interval. It is probable, that, except for a short episode spanning from 36 000 to 30 000 cal yr BP during which forest types occur, the landscape around Sacred Lake remained open and similar to that of the modern ericaceous belt. From 16 500 cal yr BP (zone 2), the progressive increase

of *Hagenia abyssinica* suggests that the treeline started to move upward. It reached the core site around 12 200 cal yr BP when *Hagenia* was associated with *Myrica*. *Hagenia* and *Myrica* are heliophilous colonizing taxa nowadays found in the ericaceous belt or at the upper limit of the forest. Their occurrence could account for an early stage of forest development at the core site. Then the disappearance of elements from the ericaceous belt and the correlative increase of *Afrocrania*, *Olea*, *Rapanea*, *Macaranga*, *Dombeya*, and *Pygeum* record the development of the humid montane rainforest in response to warmer and moister climate conditions (zone 3). Finally, toward the top of the sequence after about 3500 cal yr BP, the dramatic increase in *Podocarpus* pollen and the decrease of pollen from humid plant types indicates the replacement of the humid forest by more dry forests around the lake (zone 4).

Mahoma is a glacial lake situated at 2960 m altitude in the Ruwenzori massif (Figure 13). It yielded a 9.5 m long core studied by Livingstone in 1967. The lake lies at the boundary between the montane forest belt and the ericaceous zone. Three main phases of vegetation development can be distinguished. At the base of the sequence, from 22 000 to 15 000 cal yr BP, the vegetation surrounding Mahoma Lake was dominated by plants from alpine grass- or scrublands mainly composed of Poaceae, *Dendrosenecio*, Ericaceae, and *Artemisia*. Of interest is the large representation of small trees and shrubs, including *Myrica*, *Hagenia abyssinica* and *Anthospermum*, which attest, as at Sacred Lake at approximately the same interval, to an early stage of plant

Figure 11 Summary pollen diagrams from Lake Tanganyika showing the last glacial–interglacial transition (core MPU-12 from the Southern Basin) and the Holocene (core Sd14 from the Northern Basin) (Data from the African Pollen Database). Reproduced from Vincens A (1989) *Paléoenvironnements du bassin North-Tanganyika (Zaire, Burundi, Tanzanie) au cours des 13 derniers mille ans: apport de la palynologie. Review of Palaeobotany and Palynology* 61: 69–88; Vincens A (1991) *Late Quaternary vegetation history of the South-Tanganyika basin. Climatic implications in South Central Africa. Palaeogeography, Palaeoclimatology, Palaeoecology* 86: 207–226.

colonization after the retreat of glaciers. The pollen from ‘alpine’ taxa markedly decreased after 15000 cal yr BP and definitively disappeared from this record around 10000 cal yr BP. They were replaced by pollen from forest plant types such as *Olea*, *Celtis*, Myrsinaceae (mainly *Rapanea*), and *Acalypha*. This pollen assemblage does not correspond to any modern analogue. Most of the taxa are elements of the present day montane forest or are found at the boundary between the forest and the ericaceous belt, whereas *Celtis* and *Acalypha* belong to vegetation associations nowadays found downslope from the montane forest. Lastly, the last four millennia record the decrease of *Celtis* and the increase of *Podocarpus* in response to probable climate deterioration. The high proportions of Poaceae pollen in the upper levels of the Mahoma pollen sequence, moreover, account for increased anthropogenic pressure and correlative forest clearance in the Ruwenzori Mountains during the last millennium.

The End of the African Humid Period

The Collapse of the Tropical and Equatorial Forests

Considerable changes in vegetation have occurred in tropical Africa during the last few thousands of years at the end of the

African Humid Period (Vincens et al., 1999). In the lowlands of the equatorial forest domain (Figure 14), the individual response of the environment at each pollen site was clearly dependent upon local hydrogeological conditions. The replacement of forests by more open landscapes, wooded grasslands, grasslands, or woodlands occurred within an interval lasting from 4500 to 1300 cal yr BP. Some lakes dried out, such as Sinnda, while other sites remained forested (Bosumtwi, Barombi M’Bo) or were only partially affected, with rain or swamp forests being replaced by more open formations with increasing importance of light-dependent trees. To the north, the development of the modern ‘Dry Dahomey Gap,’ which interrupts the Guineo–Congolian forest domain, dates from 4000 cal yr BP (Lake Sélé; Salzmann and Hoelzmann, 2005), whereas the disappearance of the gallery forests from the Manga area in northern Nigeria took place at a date varying from roughly 4500 and 3500 cal yr BP and from the western Sahel only at around 2500 cal BP (Diogo 2, Figure 6). In this latter area, specific hydrological conditions linked to the proximity of the sea partly explain the persistence of dense forest communities more than 2000 years after the onset of dry climate condition over the Sahel. New high-resolution pollen data from Cameroon (Lake Mbalang (Vincens et al., 2010); Lake Bambili (Assi-Kaudjhis et al., 2008; Lézine et al., in preparation)) confirm

Figure 14 The end of the African Humid Period in western Africa. The vegetation response to the 4000 yr BP dry event varied considerably according to the local hydrological settings and occurred within a span of 2500 years. Reproduced from Vincens A, Schwartz D, Elenga H, et al. (1999) Forest response to climate changes in Atlantic Equatorial Africa during the last 4000 yr BP and inheritance on the modern landscapes. *Journal of Biogeography* 26: 879–885.

the ‘threshold’ effect in most of the forest response to the climate deterioration at the end of the African Humid Period. The dramatic switch from forest to grassland communities occurred ca. 3000 cal yr BP at both sites after a long period of progressive forest destabilization starting in the mid-Holocene in response to superimposed climate fluctuations. These included a long-term gradual decrease of summer insolation and the short-term variability likely linked to El Niño/Southern Oscillation and sea surface temperature changes in the tropical Atlantic (Jury et al., 2002; Moy et al., 2002).

The Retreat of Tropical Trees from the Saharan Desert

The discovery by Kröpelin et al. (2008) of a groundwater-fed lake in the hyperarid desert of northern Chad was important because the lake yielded a unique continuous sedimentary sequence of late Holocene age for the entire Saharan desert. It significantly improves our knowledge of Saharan paleoecology, particularly with respect to the adaptation of plants to the shift from moist to arid conditions and the setting of the modern Saharan desert. The Lake Yoa pollen record (19°02'N, 20°19'E; Figure 15) shows the progressive retreat of tropical plant communities, which were widely spread throughout North Africa (Watrén et al., 2009) during the African Humid Period, and their replacement by herbaceous-dominated desert ecosystems. The occurrence between 6000 and 4750 cal yr BP of pollen from numerous tropical plants together with ferns and other indicators of surface runoff indicates a dominant monsoonal climatic regime. Their low percentages, however, show that dense tropical forest formations never existed at the time. Trees likely occurred as gallery forest in an open landscape, characterized by extended herbaceous plant communities dominated by grasses and containing numerous Saharan and Sahelian elements.

From 4750 to 2700 cal yr BP, a transition zone, characterized by the disappearance of most of the tropical humid indicators and their replacement by Sahelian (Sudano-Sahelian, then

Sahelo-Saharan) elements including *Tribulus*, *Boerhavia*, and *Blepharis*, which are therophytes (annual plants) with a very short life cycle (Gillet, 1968) and thus well adapted to long rainless periods, confirms the increasing intensity of dry environmental conditions. Then, after 2700 cal yr BP, the increase in psammophilous (sand-loving) plant types (mainly *Cornulaca*, *Ephedra*; White, 1983) confirms the local expansion sand dunes around Lake Yoa and the establishment of modern climate conditions characterized by the complete reversal of prevailing winds, which are predominantly in the NE–SW direction.

Concluding Remarks

This review of postglacial pollen records from the African tropics highlights two major observations:

- (1) Pollen data reported here show that the African ecosystems were highly sensitive to climate change. The impact of climate changes was not only the upslope and down slope displacements of existing vegetation belts in the eastern highlands or the northward and southward displacements of existing phytogeographical zones in the western lowlands. As observed by Livingstone (1967, p. 50), “...taxa appear to have behaved individually rather than as members of a migrating community.” As a consequence, the biodiversity of the African ecosystems was considerably more diverse during the last few thousands years, during the last glacial stages, and during the Holocene than at present.
- (2) The presence of available fresh water in interdunal depressions and the reactivation of extensive fluvial systems during the early Holocene, which was linked to enhanced monsoonal rainfall, allowed tropical trees to migrate north and to persist for several thousand years in the Saharan desert. The role of local hydrological conditions has to be carefully taken into account when interpreting pollen data in terms of climate parameters.

Figure 15 Lake Yoa summary pollen diagram (Ounianga lakes, Northern Chad) showing percentages of main pollen types. Grey shading indicates 10 × magnification. Introduction

Geological, Climate, and Biogeographic Setting

Australia and New Zealand had similar positions in terms of latitude and proximity to Antarctica until the late Cretaceous, with all these regions located in high southern latitudes under the influence of westerly air flow. From the occurrence of forests of various conifers and with *Nothofagus* prominent among the angiosperms, it is likely that they had moist and mild climates. New Zealand separated from this connection about 80 Ma and Australia from Antarctica about 35 Ma, and from these times the two regions had different floristic histories.

The Australian region of the Indian–Australian Plate drifted northward into the mid-latitudes and tropics. By the Pliocene, only the south and Tasmania remained under the influence of the westerlies, and the climate of a large part of the continent was dominated by the influence of a subtropical high, causing a large area to become arid, and the far north to come under a monsoon climate. The flora diversified rapidly under these conditions, rainforests and particularly the conifers decreased in extent, while *Eucalyptus*, *Acacia*, and *Banksia* woodlands and heaths developed and arid shrublands and grasslands gained prominence. During this interval, there was very little landscape renewal and soils became depleted in nutrients through leaching.

In New Zealand, the climate remained firmly controlled by its position in relation to the westerlies, but the central spine of mountains allowed a relatively drier eastern South Island environment to develop. The high mountains, mid-southern latitudes, maritime environment, and active volcanism and with regular regionally extensive glaciation from the late Tertiary meant that New Zealand had relatively regular landscape renewal compared to Australia. This resulted in much more nutrient-rich soils, no strongly seasonal drying cycle, and hence a better environment for forest.

A consequence of Australia's drift northward was that it also came in contact with Asian floras and faunas. New Zealand was much more isolated so there was some limited exchange between Australia and Asia but very little between New Zealand and anywhere else. By the late Tertiary, New Zealand's flora had retained a strong similarity with its early Tertiary and Australian counterparts, while for Australia many new environments and adapted floras were in place. The long period of isolation meant that both regions developed highly endemic floras. Several glacial–interglacial cycles took place from the late Pliocene, and in the very latest part of the Quaternary human impacts caused natural systems to be subjected to prolonged environmental perturbations. It is the last phase of these events that the present contribution considers.

Lead-up to the Last Glacial Maximum

The last great glacial cycle began about 125 ka, and in MIS 5e the global climate was relatively warm. From about 100 ka, there was a general trend of cooling toward the Last Glacial Maximum (LGM), centered around 21 calendar ka. The climate changes toward this pivotal time were not straightforward. Every study shows a great deal of climate variability, with abrupt events, relatively warm intervals, and relatively cool intervals, of various time spans and severity along the way (e.g., [Alverson et al. \(1999\)](#), [Bradley \(1999\)](#), and [Alley \(2000\)](#)). The big changes are known to be controlled by changes in Earth's orbital parameters ([Hayes et al., 1977](#)). The scale of changes that occurred on submillennial timescales are still questions of debate. There remains some uncertainty of the actual timing of the peak of LGM. Some glaciers in New Zealand, for instance, seemed to have reached their maximum size several thousands of years before 21 ka BP.

The LGM pattern in Australia is one of general aridity rather than of ice cover as occurred for much of Europe and northern North America. The extent of ice in Australia was small, being restricted to the mountainous southeast and in Tasmania. Similarly, the direct impact of ice on vegetation was small; however, periglacial conditions and increased continentality had strong regional impacts in some areas. Inland Australia and indeed many now-humid areas were so dry at the LGM that few sites of pollen deposition have been found. Thus, the database for reconstruction of vegetation at the LGM is small. Broad land bridges from the mainland to New Guinea and Tasmania created a land surface about 30% greater than today; opportunities for migration of plants, animals, and humans were enhanced.

The vegetation patterns, especially in the south, were greatly modified by these environments. A large part of southeast Australia was converted from forest and woodland to a semi-arid steppe, dominated by grasses, Asteraceae, sometimes chenopods, and only small numbers of forest or heathland species were present (see [Figure 1 \(a\)](#)). It appears that for the south-west, heath and woodland taxa survived right through the LGM. There was no ice in that region, and no great increase in continentality. It is possible that the very high biodiversity led to some inbuilt resilience to conditions at the time so that although species composition changed, no great shift in vegetation structure occurred. For latitudes less than about 30°S, along the eastern coast, there is less evidence of grassland and steppe, and woodland and forest formed the main natural vegetation structure as it does today. In most cases, the vegetation had a drier aspect to it; thus, rainforest areas seemed to be replaced by *Eucalyptus* woodland. There are no reliable records from the arid interior for the LGM – it may be that these areas

Figure 1 Estimate of vegetation cover for (a) Australia and (b) New Zealand at Last Glacial Maximum. (a) 1. Tropical rainforest (evergreen or semievergreen forest of humid tropics, usually tall) (corresponds to Olson seasonal tropical forest and broadleaved humid forest. Also includes swamp forest). Leaf cover above a level 8 m off ground, >50%. No more than 50% loss of canopy leaf cover at any one time during average year. 2. Monsoon or dry forest (medium height, deciduous or mainly deciduous forest of warm climates) (not corresponding to an Olson category; approximately a subdivision of seasonal tropical forest). Leaf /branch cover above a level 8 m off the ground, >50% during peak month of leafiness. >50% loss of canopy leaf cover at some stage in average year, except for Australian *Eucalyptus* dry forests, where limit of rainforest is defined by where *Eucalyptus* becomes >50% of canopy. 3. Tropical woodland. 4. Tropical scrub. 5. Tropical semidesert (sparse scrub or sparse grassland) (Corresponds to subdivision of Olson desert and semi-desert). Less than 2% vegetation cover above 80 cm off the ground. 25–4% vegetation cover between 0 and 80 cm off the ground, during an average year. 9. Savanna (dense grassland with a scattering of trees and/or bushes) (subdivision of Olson tropical savanna and woodland). 12. Montane tropical forest (evergreen, adapted to cool temperatures) (not corresponding to an Olson category). 18. Semiarid temperate woodland or scrub (various open woody vegetation types) (corresponds to Olson warm conifer and other woodlands). (18a = temperate woodland, 18b = temperate scrub.) Cover above 8 m, less than 20%. Cover 0.8–8 m, above 20%. 23. Temperate semidesert (sparse shrubland or grassland) (subdivision of Olson desert and semidesert). 4–25% total above ground cover. 29. Lakes and open water. (b) Reproduced from McGlone MS, Salinger MJ, and Moar NT (1993) Paleovegetation studies of New Zealand's climate since the Last Glacial Maximum. In: Wright HE Jr., Kutzbach JE, Webb T III, et al. (eds.) *Global Climates since the Last Glacial Maximum*, p. 301. Minneapolis: University of Minnesota Press, with permission from University of Minnesota Press.

also gained a drier aspect, perhaps becoming more open in structure. However, these regions today see great variability in rainfall and it may be that very little change took place. In short, the overall picture suggests a reduction in biomass, and, although climate seems to have driven this, it is not clear if reduced CO₂ was also a factor.

For New Zealand, lowered sea level joined the main islands into an area the size of a small continent (Figure 1(b)). A substantial ice cap covered South Island and high mountain areas in North Island at places like Mt. Egmont and the central volcanic plateau. New Zealand, then, does have a genuine postglacial history as opposed to most of Australia. Periglacial conditions were widespread, and large parts of the South and central North Island were covered by grasslands. Small patches of scrub and forest probably survived in protected valleys. True forest was restricted to the north, perhaps in latitudes north above 38°S (Figure 1(b)).

Recovery from the LGM

Recovery from the LGM grasslands and steppe, as viewed in terms of vegetation change, was most likely a process that had several phases. Initially the changes were small: increasing numbers of shrub and tree pollen in the south, gradual conversion of grasslands into shrublands, then shrublands with scattered trees. Examples of this from Tasmania, South Island, and southeast mainland Australia are shown in Figure 2. Around the present rainforest areas of both Australia and New Zealand, small numbers of rainforest taxa appeared or even survived in LGM refugia. About 10 radiocarbon ka, a significant change took place. Tree numbers increased rapidly in all areas where woodland and forest occur today. This coincides with many lake systems becoming permanent water bodies after being largely dry basins, sometimes associated with active dune fields, throughout the LGM. This is a clear indication that precipitation values were approaching modern (Harrison and Dodson, 1993).

Some effort has been spent in trying to identify a Younger Dryas signal in records from both Australia and New Zealand (e.g., McGlone (1995)). No clear indication of this has been observed; indeed, no major or significant changes have been identified in the interval, such as Heinrich Events, causing change in vegetation cover or vegetation recovery after the LGM. Perhaps these phenomena were not significant in the region; the vegetation histories examined so far have suffered from lack of sensitivity or the sites have insufficient time resolution to resolve the matter. Examples of high resolution records for the interval 15–10 ka are shown in Figure 3. These generally indicate small degrees of change that were little different from the degree of change observed for much of the Holocene.

Patterns of Change in the Holocene in Australia

The Holocene opens with the main patterns of vegetation close to modern for large parts of Australia. This means that since the LGM, significant adjustments involving migration and

re-establishment had occurred during about 8 radiocarbon ka, an interval almost as long as the Holocene itself.

In southeast Australia, the majority of detailed records are from the Western Basalt Plains of Victoria and adjacent south-east South Australia. This largely reflects the abundance of sites in close proximity to several research centers. The Basalt Plains is an area dominated by cracking clays. This excludes many plant species that might otherwise be suited to the Mediterranean-type climate of mild moist winters and hot dry summers, and probably gives a distorted view of vegetation change when it is applied widely across the region. From the early Holocene, woodland was already established (e.g., Dodson (1979)). The understorey of the woodlands had a relatively open character and that was maintained through the Holocene. The greatest shifts in vegetation structure occurred after the time of European settlement. In mountainous regions of northeast Victoria and southern New South Wales, the early Holocene opens with woodland and shrubland and a mid-Holocene interval with evidence of expanded moist and relatively warm taxa such as *Pomaderris* spp. (native hazel tree) (e.g., Martin (1999)). However, there is no clear evidence of expansion of alpine *Eucalyptus* species above the present snowline (at about 1800 m a.s.l.), so this change is regarded as having had small dimensions. In the Barrington Tops region of central-eastern New South Wales, this same mid-Holocene period was marked by a small expansion of temperate rainforest taxa. From about 4 ka BP, the vegetation opens up again, with snow grasses being more prominent and this has been regarded as associated with a slight cooling and drying. This pattern was reversed after 1.5 ka BP, and is associated with renewed peat growth. It is hypothesized that this is due to decreased evaporation (Dodson et al., 1986; Dodson, 1987). There may be a role for fire in the dynamics of these patterns but the extent of this is not clear.

Tasmania is treated separately here because its vegetation contains a significant number of endemic conifer and podocarp species. The early Holocene opens with mixtures of woodland and shrubland (e.g., Macphail (1979)). Then, within a thousand years, there is an expansion of more mesic vegetation, and from the mid-Holocene a cooling trend is evident as grassland taxa expand and *Pomaderris* declines. Much of the vegetation is very sensitive to the frequency, intensity, and probably seasonality of the fire regime, and many records do not include fire histories to see the impact of these. Cooling in the late Holocene and the expansion of wetland may have expanded the area of fire shadow habitats and allowed for greater development of *Athrotaxis* (pencil pine) woodlands and forest, as seen at Solomons Jewel Lakes where expansion of *Athrotaxis* follows *Sphagnum* hummock and hollow formation (Dodson, 2000).

The Atherton Tableland of northeast Australia has rich soils and it is moist all year due to the Australian monsoon and winter trade winds. The natural vegetation is dominated by tropical rainforest. The area was probably covered by sclerophyll forest (woody evergreen plants having leaves that are hard and tough, so reducing the rate of water loss) and remnant rainforest patches at LGM. In the early Holocene, the dominance of rainforest over sclerophyll forest took about 2–3 ka. This trend is assumed to be a lag effect due to the relatively slow migration of rainforest taxa from LGM refugia; in other words, vegetation change significantly lagged the trend

in climate (e.g., Kershaw (1983)). After about 3 ka BP, there is a reduction in rainforest taxa which may be related to increased burning by Aboriginal people, a slight drying of the climate, or both (Kershaw, 1986).

At the Top End, in the Northern Territory, there are few records and these all come from the late Holocene. Most of these come from coastal plains and mainly reflect marine transgressions and sedimentation regimes. Rapid sedimentation

began about 7–6 ka BP, and the records are dominated by mangrove pollen (e.g., Crowley et al. (1990)). Continued sedimentation gradually changed the environments to freshwater swamps, especially after about 5.3 ka BP, with occasional marine incursions. The regional terrestrial vegetation signals are generally swamped but where present suggest *Eucalyptus* woodlands and rainforest taxa, as is the case today (Woodroffe et al., 1986; Clark and Guppy, 1988).

Figure 2 (a) Pollen diagram from Eagle Tarn, Upland Tasmania (redrawn from Macphail MK (1979) Vegetation and climates in southern Tasmania since the last glaciation. *Quaternary Research* 11: 306–341).

Figure 2 (b) Pollen diagram from Durham Rd, North Island, New Zealand (redrawn from [McGlone MS \(1995\)](#) Lateglacial landscape and vegetation change and the Younger Dryas climatic oscillation in New Zealand. *Quaternary Science Reviews* 14: 867–881). (c) Examples of Holocene-age pollen diagrams from Australia Bega Swamp, New South Wales (redrawn from [Hope GS, Kershaw AP, et al. \(2004\)](#) History of vegetation and habitat change in the Austral-Asian region. *Quaternary International* 118–119: 103–126).

There are few Holocene records of vegetation change in the semiarid and arid regions of Australia. In some cases, they come from peats associated with groundwater discharge and are therefore associated with very local wetlands. Until the records are better developed, the degree of impact on vegetation as recorded for southeast Australia, and accordingly the recovery from LGM conditions was more subdued. The main change seems to be that *Casuarina* became less important during the Holocene while *Eucalyptus* became more important. The reasons for this are unclear. It is unlikely to be a trend in soil leaching because most of the landscape has ancient and highly leached soils. Because of the high biodiversity of the region, and the low resolving power of pollen analysis in identifying potential *Casuarina* or *Eucalyptus* species in this transition, it is difficult to target the possible causes of the change beyond possible successional change. *Casuarina* is a nitrogen fixer and the later expansion of *Eucalyptus* may depend on subtle changes in soil nitrogen balance. No clear relationship between possible fire regime change and vegetation change has been identified for the region.

In summary, the records from Australia show a series of subtle vegetation changes across the Holocene. Apart from the southwest, there is a general pattern of an increased mesic interval in the early to mid-Holocene, which appears to show differences in timing from place to place. The differences in

timing for the beginning of this phase may depend on real regional differences in the establishment of climate patterns, but could also be related to lag times for key taxa to migrate into those regions after the LGM. The differences in timing at the end of the mesic phase may be related to a combination of climate shifts and innate resilience and subsequent reaction of vegetation to new conditions. It is possible that fire, perhaps in combination with climate and anthropogenic impacts, may have been important at some sites in setting the actual timing of changes, although it is a debated topic (e.g., Hallam (1975) and Horton (1982, 2000)). The southwest-southeast differences may relate to the fact that inbuilt resilience in the former could be due to the high biodiversity, which allowed many related species to fill gaps in times of change. In this case, some of the change goes unnoticed because it is difficult to observe with the taxonomic resolving power of routine palynology. It is known that even in the Tertiary, fire regimes in the absence of humans were only a little different from the historical period (Atahan et al., 2004; Dodson et al., 2005)

Patterns of Change in the Holocene in New Zealand

For most of New Zealand, the Holocene opens with many vegetation types about to undergo further significant change

Figure 3 Estimated vegetation cover during the Holocene optimum for (a) Australia and (b) New Zealand. (b) Reproduced from McGlone MS, Salinger MJ, and Moar NT (1993) Paleovegetation studies of New Zealand's climate since the Last Glacial Maximum. In: Wright HE Jr., Kutzbach JE, Webb T III, et al. Figure 3 (Continued)

before they assume their modern character. Central North Island and South Island have a Holocene history initially dominated by recovery from LGM conditions, and with possibly periodic interruptions from volcanism in the North Island. Forests survived LGM in the far north, above about 38° S, and Holocene vegetation changes were more subtly related to climate rather than dominated by a recovery mode.

In the early Holocene, some southern sites open their records with shrubby taxa such as *Halocarpus*, *Myrsine* (matipo), *Coprosma*, or *Phyllocladus* (celery pine) species, and especially near subalpine areas there is a strong grassland element (Figure 4). These then become dominated by one or more tree Podocarpaceae taxa, such as *Podocarpus-Prumnopitys*, and *Dacrydium cupressinum* (rimu). Some sites have early Holocene records with forest already established and presumably these were near forest refugia at the LGM. Then, depending on location, *Nothofagus* spp. (southern beech) begin to appear, before the early Holocene. In some places afforestation was rapid, especially in central North Island and northern South Island, and a few thousand years later in southern and eastern South Island. There is a pattern of establishment that probably reflects migration from refugia, mainly in the mountains

around southern North Island, Nelson, and possibly southland. The migration rates were slow but when *Nothofagus* appeared it grew to dominate the forest canopy and its dense nature created low light conditions at ground level, ultimately leading to the elimination of podocarps. Subsequently, large areas of forests were dominated by one or more *Nothofagus* species. On the lowlands of central western South Island, *Nothofagus* was not present in the Holocene (it was about 30 ka BP). The region is still dominated by tall podocarp forests and sometimes the region is referred to as the beech (*Nothofagus*) gap (see Figure 4 for examples). Other small regions remained occupied by podocarp forests, for example, some wetlands occupied by *Dacrycarpus dacrydioides*, or shrublands in areas adjacent to large active braided streams.

In addition to these changes, there was one other significant change noted for some central and northern sites. This was an increase in *Ascarina lucida* (hutu), a shrub to small tree that is frost sensitive. In many pollen diagrams, there is an early Holocene interval of greater abundance of *Ascarina* (see Figure 4). The decline after about 6 ka BP (McGlone and Moar, 1977) is thought to represent a cooling or more frost-prone environments after this time.

Figure 4 Examples of Holocene-age pollen diagrams from New Zealand: Maratoto (North Island), and Bell Hill and Crooked Mary Creek (South Island). Reproduced with permission, University of Minnesota Press.

Northern New Zealand retained forest cover during LGM, probably as a result of the maritime environment and warmer climate in the region. The vegetation adjustments in the post-glacial were therefore much less than further south. Pollen diagrams show that *Agathis australis* (kauri) was present and that *Nothofagus menziesii* (silver beech) was prominent (e.g., Dodson et al. (1988), Kershaw and Strickland (1988), and Newnham (1999)). During the Holocene, only small vegetation adjustments appear to occur for these regions.

Anthropogenic Impacts

Australia and New Zealand had vastly contrasting human histories and hence human impacts on vegetation. The evidence suggests that humans arrived in Australia from Asia about 55–60 ka BP. People occupied most of the continent before LGM and had thus adapted to the full range of environments, and had coped with full glacial conditions that were severe in the south, and most especially in the southeast. In stark contrast, humans arrived in New Zealand within the last thousand years. In this case, the people were of Polynesian origin and were spreading to their most southerly location, well beyond their original homelands in the tropics. They brought their crops and fishing methods with them, and although the environment was different from the tropical and subtropical Pacific, they did not need to weather any great climate or natural habitat shifts, that were not of their own making, after settlement. European settlement began in both countries about 200 years ago. Native people were displaced, and new forms of agricultural practices and urbanization took place, which initiated a series of major and probably irreversible changes in the environments.

The long period of Aboriginal occupation of Australia before the Holocene appears to have led to long-standing patterns of land use, burning, and hunting. Accordingly, it is difficult to identify any vegetation adjustments that relate specifically to changing patterns of human impact in the Holocene. A long-standing debate is the timing of the demise of a large browsing and grazing fauna termed the Australian megafauna (see [Late Pleistocene Megafaunal Extinctions](#)). Although there are some Holocene dates, these are possibly unreliable and it is likely that the megafauna were extinct by the late Pleistocene. Interpretation of possible adjustments in vegetation composition and structure related to these is fraught with the difficulty of matching the timing of the extinctions with climate change and human impacts such as hunting. Present knowledge suggests this as a late Pleistocene question rather than a Holocene one. One thing we do know is that recent work suggests that burning patterns were already well established before the Holocene.

Polynesian settlement had a very strong impact on vegetation systems in New Zealand. People arrived into a well-forested landscape (below tree-line) and began clearing for agriculture and hunting of the large and abundant bird fauna. The birds were naïve and apparently easily hunted to extinction ([Anderson, 1989](#)). Consequently, major changes in vegetation cover took place, and most of this occurred within a few hundred years. The scale of human impact was more severe in South Island, where forest recovery rates may have been

lower in the cooler conditions compared to the north. Wood charcoal is very abundant in the soils and it is clear that fire was an important tool used by people to clear forests for crops and an aid in hunting. The megapode birds became extinct in a short period due to hunting and loss of habitat.

European settlement began in Australia and New Zealand in the late eighteenth century, and from about AD 1840, much of the good soils were being utilized for agriculture and human settlements. In pollen diagrams, the first signs of European settlement are associated with clearing of woodland and forest, the establishment of grassland, and the introduction of many new species, including weeds. The latter include *Pinus*, *Plantago*, and *Echium*, plus sometimes an increase in native species such as *Pteridium*, which were favored by clearing ([Figure 5\(b\)](#)).

Some Outstanding Questions

Several late Pleistocene and Holocene abrupt and relatively short-lived climate events are widely recognized in many records from the Northern Hemisphere. These include Dansgaard–Oeschger events, the Younger Dryas cold interval, and the 8.2-ka and 4.2-ka dry and cool events, the Medieval Warm Period and the Little Ice Age. It is important to establish whether these can also be identified in Australia and New Zealand and thereby distinguish whether these were events caused by regional- or global- scale mechanisms. For those that are not represented globally, more regional explanations need to be identified for their causes. In all cases, there is no unequivocal representation of these events in either New Zealand or Australia. The reason for this is not clear; possible explanations include that they were of such minor magnitude that their effects were minimal, or perhaps the time resolution of the records studied so far has been too coarse to reveal them, or perhaps the long evolution of the floras of the region in isolation has predisposed the floras that have been studied to show little reaction to these events. If this is the case, then proxy data series unrelated to vegetation change may be necessary to identify them.

A major question attracting attention is the significance of fire in the environment, and the role of humans in changing its frequency, intensity, and patterns. It is generally considered that this was important in shaping vegetation and environments in Australia and New Zealand, but probably at different times. New Zealand is a wonderful laboratory for testing human impacts. We know that the changes wrought since European settlement have created environments that have proved to be hostile to most native plant and animal species. Since Polynesian settlement, perhaps 700 years ago, significant amounts of clearance, at least accompanied by fire, have been the norm. Natural fire was associated with volcanism and lightning, but because there were no anthropogenic effects before 700 yr BP, it becomes possible to investigate records for their dynamics and trends in comparison with the modern day. Research in this area will undoubtedly open up insights in to how systems work, and enable environmental managers to make better informed decisions on biodiversity, conservation, and on the dynamics of natural systems.

Introduction

Northeastern North America (NENA) is here defined as all US states and Canadian provinces east of 100° W that were wholly or partially covered by the Laurentide Ice Sheet at the Last Glacial Maximum, ca. 21 000 cal yr BP (21 ka). The many lakes, mires, and hollows in this deglaciated landscape have made NENA a center of palynological research for six decades, with over 500 NENA records archived in the Neotoma Paleoecology Database (Figure 1) (Grimm et al., 2013). This dense network permits detailed reconstructions of the spatial and temporal patterns of postglacial vegetation history. Plant taxa exhibit highly varied postglacial vegetation histories, characterized by large shifts in range and abundance, and relatively rapid rates of change between 16 and 8 ka (Jacobson et al., 1987; Shuman et al., 2005; Williams et al., 2004). Higher-order vegetation characteristics, such as biomes, plant functional type distributions, and associations among plant taxa, emerge from the individualistic behavior of plant taxa. Comparison of pollen records with independent paleoclimatic proxies indicates that NENA vegetation history has been primarily shaped by climatic variability at centennial to orbital timescales and by the postglacial opening up of new lands for colonization caused by the retreat of the Laurentide Ice Sheet. Other contributing factors include variations in atmospheric CO₂ concentrations (Cowling, 1999), the late Pleistocene megafaunal extinctions (Gill et al., 2009), and human land use (Denevan, 1992; Foster, 2002).

This article first reviews the history of NENA palynology, with respect to methodological advances and insights gained into the processes governing long-term vegetation dynamics. Pollen abundance maps for selected taxa illustrate postglacial vegetation history, and community-scale vegetation dynamics are represented by rate-of-change maps, maps of the minimum dissimilarities between fossil and modern pollen spectra (which indicate past vegetation formations with no modern analog), and reconstructed maps of woody cover. Finally, this article focuses on New England as a case study of the linkages between late Quaternary vegetation dynamics and climatic variability at centennial to millennial timescales. Space constraints and the rich history of palynological research prohibit a full review of all facets of NENA vegetation history, so interested readers are directed to other syntheses and reviews (Foster, 2002; Gaudreau and Webb, 1985; Grimm and Jacobson, 2004; Grimm et al., 2001; Jackson et al., 1997; Jacobson et al., 1987; Richard, 1993; Ritchie, 1987; Shuman et al., 2009; Webb, 1988; Webb et al., 1993b; Williams et al., 2004), as well as to the primary data stored in the Neotoma Paleoecology Database.

Climate and Physiography

NENA encompasses significant north–south and east–west gradients in climate and a diversity of bedrock types and glacial

deposits. Indices of air temperature, radiation flux, and winter severity (e.g., mean temperature of the warmest and coldest months of the year, growing-degree days, number of frost-free days, potential evapotranspiration, day length) trend from north to south. Indices of moisture availability (e.g., annual precipitation, relative humidity, rainfall variability, and actual evapotranspiration) generally increase from west to east. Gradients of moisture availability are particularly steep between 100° and 95° W, with mesic conditions to the east.

Topographic relief in NENA is generally low (Bostock, 1970; Fenneman and Johnson, 1946). The Precambrian Laurentian Shield underlies most of eastern Canada and portions of the northern United States and is generally characterized by low relief and an average elevation of 500 m, although areas of locally high relief occur in the Adirondacks and the Tomgat Mountains of Labrador. In the Appalachian Mountains, ranging from Newfoundland to Alabama, elevations exceed 1500 m. West of the Appalachians, the folded sedimentary rocks of the Valley and Ridge structural province give way to the generally low-relief landscape of central North America. Although relief is generally low to moderate in formerly glaciated areas, the irregular depth and texture of glacial deposits produces variable edaphic conditions at local to regional scales.

The subcontinental-scale distribution of vegetation in NENA prior to European settlement was strongly shaped by the intersection between the north–south temperature and east–west moisture gradients, with finer-scale ecological variation due in part to the patchwork of glaciogenic and periglacial sedimentary deposits and exposed bedrock. In the semiarid upper Midwest, grasslands predominated, with the prairie–forest ecotone trending NW–SE from Manitoba to Indiana. Treeless conditions also prevail in northern Québec and Labrador, where cold winter temperatures and short growing seasons limit tree growth. Forests in NENA are characterized by a strong south-to-north zonation in species composition and physiognomy, from the deciduous forests of the east-central United States to the mixed hardwood–conifer forests in New England and Great Lakes region, to the coniferous forests of eastern Canada (Küchler, 1975; Rowe, 1972). North of 50° N, tree density decreases, as the vegetation gradually changes from closed boreal forests to lichen woodlands to forest–tundra to open tundra. Within each of these broad vegetation formations, there is substantial variation in plant community composition and structure.

History of Palynological Research in NENA

Prior to the advent and widespread application of pollen analysis in the mid-twentieth century, inferences about postglacial vegetation history were primarily based upon the distribution of extant vegetation formations, in particular the

Figure 1 Mapped percent pollen abundances for (a) *Picea* (spruce), (b) *Pinus* (pine), (c) *Ostrya/Carpinus* (hophornbeam/hornbeam), (d) *Fagus* (beech), and (e) *Ambrosia* (ragweed). Data from Williams et al. (2004).

distribution of outlier vegetation types, which were interpreted as relicts of previously continuous distributions or as pioneer communities. Before radiometric dating was available, palynologists concentrated on testing the prevailing theories of plant biogeography and plant succession, honing pollen taxonomy, and developing regional pollen stratigraphies for the purposes of stratigraphic correlation. Initial investigations were focused in New England, where Deevey (1939) established a still-cited regional pollen stratigraphic zonation, and in the upper Midwest, where Potzger (1946) collected 25 pollen records to test theories about climax vegetation type and post-glacial plant migration. Other early workers included Cushing, Davis, Leopold, Ogden, Sears, Terasmae, Whitehead, and Wright.

The application of radiocarbon dating to organic sediments soon freed pollen data from their role as stratigraphic correlators and allowed new hypotheses to be tested about the synchronicity or time transgression of vegetational events. The number of pollen analysts and pollen records rapidly proliferated during the 1960s and 1970s, providing the foundation for regional- to subcontinental-scale vegetation reconstructions. In the upper Midwest, transects of radiocarbon-dated pollen diagrams demonstrated the eastward expansion of the prairie during the mid-Holocene (McAndrews, 1966). Davis (1976, 1981b) was the first

to map pollen abundances and show time-transgressive changes consistent with a general pattern of postglacial migration and expansion. Inferred migration rates were surprisingly rapid – on the order of 100–500 m year⁻¹ (Davis, 1981b) – although these estimates may be too high (McLachlan et al., 2005). Moreover, species exhibited individualistic responses to climate change (Cushing, 1965; Davis, 1981b), overturning the previous Clementsian paradigm that vegetation formations responded cohesively to climate change (Braun, 1950). In a classic example, *Tsuga canadensis* expanded into New England several thousand years before *Fagus grandifolia* (Figure 1(d)), despite their close modern association (Davis, 1981b).

Advances during the 1970s and 1980s expanded these mapping efforts and developed statistical techniques to extract quantitative paleoenvironmental information from pollen data (Bartlein et al., 1984). These advances were enabled by the consolidation of fossil pollen records into centralized databases and the collection of thousands of surface pollen samples into calibration datasets that documented pollen-climate and pollen-vegetation relationships (Whitmore et al., 2005; Williams et al., 2006). These pollen databases are still actively supported and used and are now incorporated into the Neotoma database (Blois et al., 2011a; Grimm et al., 2013). Early work showed that the principal axes of variation in the

composition of surface pollen samples corresponded to those for the surrounding vegetation (Webb, 1974) and that pollen abundances positively correlated to plant population density (Delcourt et al., 1984). Primary emphasis soon shifted to pollen-based paleoclimatic reconstructions (Bartlein et al., 1984) and the use of such reconstructions as an independent benchmark for paleoclimatic simulations produced by general circulation models (COHMAP Members, 1988; Webb et al., 1993a). Pollen-based paleoclimatic reconstructions continue (Bartlein et al., 2011) but must now take into account the effects of low glacial CO₂ concentrations on plant physiology (Wu et al., 2007) and the possibility that the realized climatic niche for species may shift somewhat over time (Pearman et al., 2008; Veloz et al., 2012). There has been a renewed interest in using pollen data as a paleovegetation proxy, for example, for reconstructing the past distributions of biomes, plant functional types, and leaf area indices (Gonzales et al., 2008; Prentice et al., 2011; Williams et al., 2011) and using these reconstructed vegetation maps for model validation.

In recent years, an increasing number and variety of paleoclimatic records have provided independent evidence of postglacial climate history, both globally and for NENA. This independent climatic framework is freeing pollen data from its role as a paleoclimatic indicator, analogous to radiocarbon dating having freed pollen from its stratigraphic role (Webb et al., 2004), and allows instead the testing of hypotheses regarding the climatic forcing of vegetational dynamics. Events interpreted from NENA pollen diagrams can be correlated to the abrupt climatic changes recorded in Greenland ice cores and elsewhere (Gonzales and Grimm, 2009; Peteet, 1995; Shuman et al., 2002; Yu, 2007). Unfortunately, intersite correlations are hampered by imprecise age constraints: most NENA records were collected prior to 1980 and were dated using conventional radiocarbon methods on bulk sediment samples, which are prone to incorporation of 'old' radiocarbon-depleted carbon from groundwater sources and can be inaccurate by thousands of years (Grimm et al., 2009). Improvements in radiocarbon dating have come from AMS radiocarbon dating techniques (with a 1 σ error typically <200 years) and careful selection of materials for dating. Cross validation analyses of pollen stratigraphic events among well-dated 'benchmark' pollen records indicate that spatial interpolations of these events carried an uncertainty of about 500 years (Blois et al., 2011b). Multiproxy analyses at single sites permit direct assessment of vegetational responses to local climatic change, with minimal stratigraphic correlation uncertainty (Booth et al., 2004; Shuman et al., 2004).

In addition to the new opportunities opened up by multiproxy studies, exciting new directions involve the intersection of traditional pollen-based interpretations of vegetation history with new lines of evidence and new theories. Contemporary patterns of genetic diversity now provide a complementary line of evidence about postglacial migrational rates and pathways and the locations of full-glacial refugia (Jaramillo-Correa et al., 2009; Soltis et al., 2006). New evidence for accelerated rates of evolutionary response to twenty-first-century climate change, evolutionary adaption in invasive species, and within-species adaptation of populations to local environments is forcing a reappraisal of the standard paradigm that evolutionary responses to late Quaternary climate change were minimal

(Davis et al., 2005; Soltis et al., 2006). The long records of ecological dynamics provided by subfossil pollen records offer the opportunity to test theories based on observation of contemporary ecosystems and their variation along spatial environmental gradients. For example, Clark and McLachlan (2003) used eight pollen records in eastern North America to argue that Holocene forest composition and plant abundance were more stable than predicted by the Hubbell theory of neutral ecological drift (Hubbell, 2001).

NENA Vegetational History

The timing and pattern of response to late Quaternary climate change and the retreat of the Laurentide Ice Sheet varied widely among plant taxa (Figure 1), although most arboreal taxa expanded in range and abundance. Cold-tolerant taxa such as spruce, pine, birch, and alder (*Picea*, *Pinus*, *Betula*, and *Alnus*) colonized areas vacated by the Laurentide Ice Sheet, and temperate taxa such as oak, hemlock, maple, chestnut, and beech (*Quercus*, *Tsuga*, *Acer*, *Castanea*, and *Fagus*) expanded from glacial refugia in the southern Appalachians, southern Coastal Plain, and Florida. However, postglacial vegetation history was not a simple northward expansion, nor was change limited to the end Pleistocene/early Holocene transition. Taxa such as pine, sage, and ragweed (*Pinus*, *Artemisia*, and *Ambrosia*) include significant east–west shifts, whereas other taxa, such as ash, hophornbeam/hornbeam, and elm (*Fraxinus*, *Ostrya/Carpinus*, and *Ulmus*) apparently peaked in abundance during the Late Glacial and early Holocene intervals and were relatively uncommon thereafter (Williams and Jackson, 2007). During the Holocene, variations in moisture availability apparently resulted in widespread impacts upon the position and character of the prairie–forest ecotone and the composition of eastern forests (Shuman et al., 2004; Williams et al., 2009). Over the last 1000 years, spruce has re-expanded into northern New England and the northern Great Lakes, and beech and hemlock abundances have declined, presumably in response to regional cooling.

Mapped sequences of pollen percentages for five taxa – spruce, pine, hophornbeam/hornbeam, and ragweed (Figure 1) – illustrate the individualistic responses of plant taxa to postglacial environmental change. The scale of these maps emphasizes vegetation change at subcontinental scales, although finer-scale phenomena are apparent as well. At this scale, pollen abundances usually are positively correlated with the regional abundance of the parent plant taxon (Solomon and Webb, 1985), so here, we use the maps of pollen abundance to infer past changes in plant distributions, while recognizing that the underlying pollen–vegetation relationships are nonlinear and regionally variable (Prentice and Webb, 1986). A second set of maps (Figure 2) shows rates of palynological change, emergence and disappearance of novel plant communities during the Late Glacial interval, and changes in vegetation physiognomy. Additional map series may be viewed in animated form at <http://www.ncdc.noaa.gov/paleo/pollen/viewer/webviewer.html> (Williams et al., 2004).

Spruce (*Picea*)

In eastern North America, spruce (*Picea*) pollen represents three species: white spruce (*Picea glauca*), black spruce (*Picea*

Figure 2 Maps of (a) palynological rate of change, (b) minimum dissimilarity from present, and the fractional areal cover for (c) woody plants, (d) needle-leaved woody plants, and (e) broad-leaved woody plants. Rates of change and minimum dissimilarities are computed using the squared-chord dissimilarity metric. Rates of change represent the within-site dissimilarities between pollen assemblages from adjacent time intervals and hence are an indicator of local rates of community turnover. The minimum dissimilarity analyses show the dissimilarity between a fossil pollen sample and its closest analog found from an all-North American dataset of surface pollen samples (Williams et al., 2001), and hence, large values indicate fossil samples with no close analog in modern pollen samples. Estimates of woody cover are calculated by application of modern-analog approaches to pollen data and remotely sensed indices of vegetation cover (Williams, 2003; Williams et al., 2011).

mariana), and red spruce (*Picea rubens*). A fourth species (*Picea critchfieldii*) apparently went extinct during the last deglaciation (Jackson and Weng, 1999). Spruce pollen is usually identified to the level of genus, although careful morphological measurements do permit species-level identifications (Lindbladh et al., 2003).

Spruce pollen (Figure 1(a)) documents the northward expansion of cold-tolerant arboreal taxa into formerly glaciated regions. At the Last Glacial Maximum, spruce pollen was most abundant in the continental interior but is common to all full-glacial NENA records. There is minimal overlap between its present and full-glacial range, indicating that spruce dynamics have been governed by both colonization into deglaciated regions and extirpation of trailing-edge populations. Some spruce populations appear to have persisted continuously in refugia (Anderson et al., 2006; Schauffler and Jacobson, 2002). Spruce pollen percentages were moderate to high across NENA from 21 to 12 ka, but declined between 12 and 9 ka as pine expanded westward and high spruce abundances became

limited to a narrow zone between pine and the Laurentide Ice Sheet. During this period, spruce rapidly migrated northwest into the corridor between the Laurentide and Cordilleran Ice Sheets (Williams et al., 2004). Early estimates of rates of *Picea* spread were as high as 2 km year^{-1} (Ritchie and MacDonald, 1986) but have been recently revised downward to 0.3 km year^{-1} (Yansa, 2006). After the collapse of the Laurentide Ice Sheet ca. 8.2 ka, spruce expanded across eastern Canada. In the late Holocene, spruce has re-expanded into interior New England, due to an increase in red spruce and a decrease in white spruce (Lindbladh et al., 2003).

Pine (*Pinus*)

Pine pollen, like spruce, was widely abundant at the Last Glacial Maximum and documents the expansion of pine species northward and westward inland into deglaciated areas (Figure 1(b)). Exactly which species is unclear; there are roughly a dozen species of pine in eastern North America, all

indistinguishable palynologically except for eastern white pine (*Pinus strobus*) because it is the sole eastern representative of *Pinus* subgenus *Strobus*. Pine pollen was present throughout NENA between 18 and 21 ka but was most abundant in the east. Between 17 and 13 ka, pine pollen abundances dropped to trace levels in the upper Midwest, and pine is absent from macrofossil records (Jackson et al., 1997), indicating that pine was regionally rare or absent. Pine then rapidly expanded westward across the Great Lakes region and upper Midwest into central Canada. Note that the apparent westward expansion of pine into the Midwest at 13 ka in Figure 1b is probably too early, due to inaccurate radiocarbon dates for some pollen records (Grimm et al., 2009). New AMS chronologies from Crystal Lake, IL, and Appleman Lake, IN, place the pine rise around 11.7 ka (Gill et al., 2009; Gonzales and Grimm, 2009). During the early Holocene, the northern limit of pine closely tracked the northward retreat of the Laurentide Ice Sheet, reaching its current position by 8 ka. Pine pollen abundances continued to increase in northern Canada during the Holocene.

Hophornbeam/Hornbeam (*Ostrya/Carpinus*)

Several NENA pollen types from temperate deciduous hardwood trees, notably hophornbeam/hornbeam (Figure 1(c)), ash, and elm, are characterized by peak pollen percentages during the Late Glacial interval and early Holocene and relatively low abundances during the middle and late Holocene. (*Ostrya* and *Carpinus* are genera in Betulaceae that are similar palynologically and are usually mapped as a single pollen type.) These taxa are important constituents of the Late Glacial and early Holocene 'no-analog' pollen assemblages (Williams et al., 2007) and during the Late Glacial interval had closely overlapping distributions with northern conifers such as spruce and larch (*Larix*). The Late Glacial/early Holocene peak abundances correspond to greater-than-present seasonality of insolation and temperature (Delcourt and Delcourt, 1994; Williams et al., 2007), suggesting that hophornbeam/hornbeam and ash flourished under warm but short summers and were able to tolerate cold winters that excluded other thermophilous taxa. Despite these variations in abundance, the northern limits for hophornbeam/hornbeam and ash were stable during the Late Glacial interval and expanded north only slightly following the retreat of the Laurentide Ice Sheet. *Ulmus*, conversely, apparently experienced both a range expansion from the southern United States into the upper Midwest, arriving by 16 ka, and a peak in pollen abundances between 12 and 6 ka.

Beech (*Fagus*)

Many temperate arboreal taxa (e.g., beech (Figure 1(d)), hemlock, maple, lime (*Tilia*), eastern white pine, oak, chestnut, and hickory (*Carya*)) that are now common in the temperate deciduous and cool mixed forests of NENA (Küchler, 1975) were regionally rare during the Last Glacial Maximum. These taxa migrated into NENA from refugia in the southern Appalachians, southern Coastal Plain, and lower Mississippi Valley (Davis, 1983; McLachlan et al., 2005), with significant differences among taxa in the migrational path and timing of arrival. Beech is a useful example because its pollen type is associated with a single species, American beech (*F. grandifolia*). Previous pollen

data syntheses have suggested that beech full-glacial refugia were located on the southern Coastal Plain or lower Mississippi Valley and that beech migrated north into New England along a coastal route east of the Appalachians (Davis, 1981b). Low beech pollen abundances suggest arrival in New England as early as 13 ka (Davis, 1969). Beech abundances begin to rise around 9 ka, several thousand years after the hemlock rise (Davis, 1969; Oswald et al., 2007), despite the currently close association between beech and hemlock. Beech pollen is found in eastern Wisconsin by 6 ka, about 2000 years after its occurrence in western Michigan, suggesting that Lake Michigan acted as a barrier to migration (Davis et al., 1986; Webb, 1987).

These pollen-based interpretations are being reexamined in light of phylogeographic analyses of extant tree populations in eastern North America, and there are some unresolved differences between the palynological and molecular data. The spatial pattern of genetic variation in beech suggests that (1) additional beech refugia existed in eastern North Carolina and perhaps as far north as northern Kentucky and (2) migration into the Midwest was primarily from the south, not the east (McLachlan et al., 2005). The phylogeographic evidence for such cryptic refugia thus suggests that fossil-based estimates of migration rate (e.g., 200 m year⁻¹ for *Fagus*) (Davis, 1983) are too high, although the current molecular-based migration rates (<100 m year⁻¹) (McLachlan et al., 2005) are based on highly conservative assumptions about starting position and duration of migration.

Ragweed (*Ambrosia*)

The mapped series of ragweed (Figure 1(e)) illustrates shifts in herbaceous abundances in the Midwest during the Holocene, which were driven by changes in moisture availability and, in the last 500 years, the effects of European land use. *Ambrosia* has many species and is a common indicator of unforested to semi-forested vegetation, whether due to aridity or anthropogenic land clearance (Grimm, 2001; McAndrews, 1988). Ragweed was present in the northern Great Plains since the Last Glacial Maximum but did not become regionally abundant until 11 ka. Ragweed abundances peak between 9 and 6 ka. Ecophysiological evidence suggests that the ragweed peak may have been caused by drier-than-present winters that amplified the ecological sensitivity to variable levels of summer precipitation (Grimm, 2001). A high-resolution record from Kettle Lake, ND, shows that ragweed abundances repeatedly fluctuated during the middle Holocene with a periodicity of 130 years (Clark et al., 2002). In New England, a peak in ragweed pollen abundances between 10.1 and 7.7 ka indicates more arid climates and increased forest openness (Faison et al., 2006).

Most modern agricultural plant species are insect-pollinated or have limited dispersal distances (e.g., maize (*Zea mays*)) and so are not well represented in lake and mire pollen records. Primary evidence of recent human land use, therefore, comes from changes in the abundance of weedy species. The dramatic increase in ragweed after 0.5 ka (Figure 1(e)) provides a particularly clear signal of European settlement and land clearance today, and the *Ambrosia* rise is widely used as an age control in the upper portion of pollen records (McAndrews, 1988). Other plant taxa displaying post-European increases in pollen abundance include the grass family (Poaceae), sorrel (*Rumex*),

and plantain (*Plantago*). Pollen records with clear evidence of Native American land clearance and burning are scarce and suggest that Native Americans had significant but localized impacts upon NENA vegetation (Ekdahl et al., 2004; Muñoz and Gajewski, 2010; Parshall and Foster, 2002). Some areas of known agricultural activity by Native Americans, such as the Mississippi River Valley, have relatively few palynological studies (Ollendorf, 1993).

Rates of Change

Rates of palynological change in NENA were high between 17 and 8 ka, with the fastest rates of change between 13 and 11 ka (Figure 2(a)). Late Glacial rates of change were high in the entire region. The rate-of-change maps reflect widespread local turnover in the identity of dominant species and the reorganization of late Pleistocene plant communities into their Holocene counterparts (Jacobson et al., 1987; Shuman et al., 2005; Williams et al., 2001). The timing and identity of the taxa involved in the community reorganizations varied regionally (Williams et al., 2004). After 9 ka, rates of palynological change decreased, although plant community composition continued to change regionally. Between 7 and 6 ka, for example, rates of change were high for Midwestern sites as the prairie–forest border shifted eastward, in New England and New York as pine declined and hemlock and deciduous forest taxa expanded, and in northern Québec and Labrador as spruce pollen abundances increased and sedge (Cyperaceae) and willow (*Salix*) abundances decreased, indicating a northward shift in treeline.

No-Analog Plant Associations and Biomes

Many Late Glacial pollen assemblages are compositionally unlike all modern pollen assemblages in North America (Figure 2(b)). These ‘no-analog’ pollen assemblages emerge from the individualistic behavior of plant taxa and indicate plant associations not present on the modern landscape (Cushing, 1965; Williams and Jackson, 2007). These assemblages are characterized by a mixture of pollen from cold-tolerant conifers (spruce and larch), deciduous taxa (ash, hophornbeam/hornbeam, hazel, cottonwood, and willow), and herbaceous taxa (sedges and sage) and are unusual for the mixture of boreal and temperate arboreal taxa, higher-than-present pollen abundances of ash and/or hophornbeam/hornbeam (Figure 1(c)), and the scarcity of pine, alder, and birch pollen. The palynological dissimilarity scores are a conservative index of the distribution of no-analog species associations because some species are not well represented in pollen records and pollen morphology typically restricts taxonomic identifications to the genus level, so that some novel species-level associations likely are obscured (Jackson and Williams, 2004).

Equilibrium niche theory predicts that these plant communities should have formed in response to environmental conditions also not found at present (Jackson and Overpeck, 2000; Williams et al., 2001), and paleoclimatic simulations suggest that the no-analog communities grew in areas with higher-than-present seasonality of insolation and temperature (Williams and Jackson, 2007). However, pollen-based reconstructions using the expanded response surface (ERS) technique, which attempts to extend pollen–climate relationships beyond the limits of

the modern climate space, do not indicate higher-than-present seasonality (Gonzales et al., 2009). This discrepancy between paleoclimatic simulations and pollen-based paleoclimatic reconstructions is not yet resolved; one possibility is that the ERS method may not fully account for shifts in species’ realized niches during periods of no-analog climates (Veloz et al., 2012). Recent work suggests that the no-analog plant communities also may be linked to the late Pleistocene megafaunal extinctions, perhaps because the megafaunal population declines released some hardwood taxa from herbivore suppression and shifted ecosystems from an herbivore-dominated to fire-dominated disturbance regime (Gill et al., 2009; Robinson et al., 2005).

Tree Cover

Pollen-based reconstructions of woody cover, based on calibrations of modern pollen data with remotely sensed vegetation datasets, show a widespread expansion in forest cover in NENA since the Last Glacial Maximum (Figures 2(c–e)) (Williams, 2003). At the Last Glacial Maximum, open forests and woodlands prevailed to the east and steppelike conditions to the west. Closed forests developed first along the eastern seaboard and expanded westward between 14 and 11 ka, then northward until 9 ka. Late Glacial forests were initially dominated by needle-leaved trees, with mixed deciduous–conifer forests established by 12 ka and broad-leaved deciduous forests established between 11 and 9 ka. The current gradient in decreasing tree cover from the boreal forest to tundra in Québec appears to have been in place by 6 ka and has been stable since then. The vegetational impacts of European land use are manifested as a widespread decrease in woody cover after 0.5 ka, particularly for broad-leaved woody taxa.

Climatic Controls on New England Vegetation History

New England offers a particularly detailed case study of the climatic drivers of postglacial vegetation history. In Deevey’s (1939) original zonation, New England pollen stratigraphies were divided into three zones: a lowermost A zone, characterized by high abundances of spruce pollen and other coniferous taxa, indicating the development of boreal forests soon after deglaciation; an intermediate B zone, characterized by a maximum in pine pollen abundances, and a C zone, characterized by high abundances of oak pollen and other temperate tree taxa. The C zone has three subzones: C-1, in which oak and hemlock abundances are high; C-2, characterized by low abundances of hemlock and rising hickory abundances; and C-3, in which hemlock abundances recover and chestnut abundances also rise (Deevey, 1939). This sequence of events is replicated in pollen records throughout southern New England.

Independent age controls and paleoclimatic records now make it possible to match Deevey’s vegetation zones to regional and hemispheric climatic events. The period of high spruce abundances is now known to date to between 13 and 11.6 ka in southern New England (Figure 3) and is linked to a return to cooler conditions in the North Atlantic and adjacent

Figure 3 Evidence for the climatic control of postglacial vegetation history in New England at orbital to centennial timescales, based on fossil pollen records and nearby independent paleoclimatic records. (a) Maximum elevation of *Pinus strobus*. (b) Davis Pond, MA, water level. In panel a, plant macrofossil records of the upper elevational limit of Eastern white pine (*Pinus strobus*) provide a paleotemperature indicator (Jackson and Whitehead, 1991; Spear et al., 1994), while in panel b, a lake level reconstruction from Davis Pond, MA, provides a paleohydrological proxy (Newby et al., 2011). Changes in these paleoclimatic proxies correspond closely to major vegetation events in the pollen record from North Pond, MA (Whitehead and Crisman, 1978).

areas during the Younger Dryas Chronozone (Oswald et al., 2007; Peteet et al., 1993; Shuman et al., 2009). Lake level records indicate that the period of maximum pine abundances occurred during an interval of cool and dry conditions, dated between 11.6 and 8.2 ka (Figure 3). The pine maximum was time-transgressive, occurring first in southern New England and propagating north (Shuman et al., 2009) and at many sites was followed by a peak in ragweed abundances (Faison et al., 2006). Modern vegetation gradients were established between 9.5 and 8 ka (Oswald et al., 2007).

During the Holocene, centennial-scale climate variability profoundly affected forest composition. The most striking event is the mid-Holocene collapse in hemlock populations, marked by a regionwide and abrupt decline in pollen abundances. At some sites, this collapse occurred in less than 10 years (Allison et al., 1986). The apparent synchronicity and rapidity of the hemlock decline, and apparent lack of an effect on other tree taxa initially led paleoecologists to suspect that the mortality was caused by a pest or pathogen outbreak (Davis, 1981a). This hypothesis was reinforced by finds of hemlock needles with damage consistent with hemlock looper and head capsules from hemlock looper and spruce budworm, all in paludified dune field sediments dating to this period (Bhiry and Filion, 1996). Although a pest outbreak remains a viable mechanism for hemlock mortality, recent evidence has suggested that hydrological variability and drought may have been the ultimate causal agents (Foster et al., 2006; Shuman et al., 2001; Yu et al., 1997). Key lines of evidence include (1) the demonstration that oak abundances in southern coastal New England collapsed at the same time as the regionwide hemlock decline, suggesting a common climatic driver (Foster et al., 2006) and (2) evidence for lowered lake levels during the interval of low hemlock abundances (Figure 3) (Shuman et al., 2001). Recent analyses of lake sediments at New Long Pond, MA, suggest a series of repeated centennial-scale droughts (Newby et al., 2009), whose onset coincides closely with the hemlock decline (Shuman et al., 2009). Transitions between New England archaeological phases also appear to correspond to these periods of vegetation and climate change (Muñoz et al., 2010). Thus, the detailed evidence from New England strongly indicates that vegetation change is directly linked to climate change, both with respect to millennial-scale shifts in vegetation composition and more abrupt, decadal- to centennial-scale vegetation events (Shuman et al., 2009).

Summary

NENA has been a major locus of paleovegetational research during the past six decades, and the resultant dense network of fossil pollen records has enabled detailed maps and other syntheses of the spatial and temporal patterns of vegetation history. Such maps reveal the now-classic observation that plant taxon responses to climate change were highly individualistic, with each taxon displaying a unique trajectory in its shifting distribution over time. Rates of change were fastest between 13 and 8 ka and plant associations with no modern analog were common until 12 ka. Vegetation changes were primarily driven by climate change but influenced also by other factors such as rising CO₂ concentrations, the late Pleistocene megafaunal extinctions, and human arrival. In New England, local- to regional-scale syntheses of paleovegetational and paleoclimatic time series offer strong evidence of climatic controls on vegetation history. Major research directions at present include the generation of new high-resolution and well-dated paleovegetational records, the establishment of independent paleoclimatic records to provide an independent climatic framework for interpreting paleovegetational data, and the synthesis of paleoecological data with new biogeographic and evolutionary theories and data.

Introduction

The vegetation history of northwestern North America (NWN) following the last glaciation is marked by several major transitions that are consistent with a rich and complex climate history. The region today supports very heterogeneous vegetation corresponding to broad-scale gradients in moisture availability and temperature and fine-scale topography in mountainous areas (Figure 1). This heterogeneity presents a major challenge for understanding the regional vegetation history because local geomorphic and climatic conditions can modify species responses to climate change at any particular site (Whitlock, 1992). Nevertheless, some common patterns have emerged from more than five decades of paleoecological studies in this region.

Our aim in this article is not to present a comprehensive summary of the wide range of findings from the hundreds of pollen records from NWN, much of which would reiterate previous articles (Table 1). Rather, we aim to highlight robust findings from a subset of records representative of broad vegetation zones. This discussion focuses on the area north of 42° N and west of the continental divide. We first describe the broad climatic gradients and the corresponding ecosystems across NWN. We then summarize the major vegetational changes based on key pollen profiles from several subregions. The history of each subregion is discussed with respect to three major climatic periods: the Last Glacial Maximum (LGM, broadly defined as the interval 25–18 ka; ka, thousands of years before present), the last glacial–interglacial transition (14.5–11.6 ka), and the Holocene (11.6–0 ka). All ages are based on calibrated radiocarbon dates.

Broad Patterns of Climate and Vegetation

The dominant westerly flow of moisture results in a major longitudinal moisture gradient due to coastal mountain ranges that produce heavy orographic precipitation to the west and a rain shadow to the east. Thus, the primary vegetation gradient is characterized by a maritime moist conifer forest west of the crest of the coastal ranges and a mixture of sagebrush steppe, mixed conifer, and pine forests east of the coastal ranges. In the southern half of NWN, little rainfall occurs from July to September, due to the dominance of a subtropical high-pressure system centered over the Pacific. This results in a seasonally dry maritime forest along the coast in Oregon and Washington, and very dry shrub steppe sagebrush in the interior. Further to the east, beyond the continental divide, summer moisture increases from monsoon-like precipitation. In the northern half of NWN and generally north of the subtropical high pressure, increasing onshore flow results in a hypermaritime coastal climate dominated by dense forests of

shade-tolerant conifers up to 60° N. In the high-snow areas along the coast, treeline declines from 1500 m in western Washington to 500 m in south-central Alaska. East of the coastal ranges, summer moisture increases with latitude due to increased summer convective precipitation, especially in mountainous areas. From south-central British Columbia northward, the inland vegetation transitions from sagebrush steppe to pine forests, then to subboreal and boreal spruce forest (i.e., the Cold Desert to Western Cordillera to Boreal Cordillera transition on Figure 1.). An exception to this overall pattern occurs to the west of the continental divide from northern Idaho to central British Columbia, where high precipitation results in a moist interior forest, often called the interior wet belt, dominated by *Tsuga heterophylla* (western hemlock) and *Thuja plicata* (western redcedar) that are disjunct from their main coastal distribution (Gavin, 2009). In central Alaska, the boreal forest is mainly composed of black and white spruce, with aspen and birch on warm and disturbed sites. In general, treeline in the interior forests is hundreds of meters higher and declines at a slower rate with latitude compared to the maritime forests. The forest limit in Alaska abuts the southern flanks of the Brooks Range and is limited westward toward the cold-maritime climates near the Bering Sea. For detailed accounts of vegetation–climate relationships in this region, we refer readers to detailed monographs focused on Oregon and Washington (Franklin and Dyness, 1988), British Columbia (Meidinger and Pojar, 1991), or Alaska (Gallant et al., 1995; Viereck et al., 1992).

Alaska

This section should be read in conjunction with [Northern North America](#).

Last Glacial Maximum

Despite the fact that much of the region was unglaciated during the last glaciation, most of the Alaskan pollen records do not extend beyond the past 14 000 years. At all of the sites where full-glacial sediments have been recovered, the pollen spectra of the LGM are dominated by Poaceae, Cyperaceae, and *Artemisia* (Eisner and Colinvaux, 1990; Livingstone, 1955, 1957; Oswald et al., 1999). These pollen assemblages are difficult to interpret because of their broad ecological tolerances (e.g., Cwynar, 1982). However, minor taxa such as *Encalypta rhabdocarpa* and *Selaginella siberica* suggest that sparse, xeric tundra prevailed under the cold, dry climate of the late Pleistocene.

An issue that remained controversial for several decades was whether some of the boreal-forest tree species existed in eastern Beringia (Alaska and adjacent Canada) during the LGM (Hopkins et al., 1981; Hultén, 1937). Based on the spatial

Figure 1 (a) Shaded-relief map of northwest North America using a color scheme that differentiates humid (green) and xeric (brown) regions. Ecoregions differentiate the major vegetation types and climatic regions. The map shows all eight ecoregions occurring within our area of focus from the ecoregions of North America (Commission for Environmental Cooperation, 1997). (b) Extent of the Cordilleran ice sheet, other ice fields, pluvial lakes, and proglacial lakes at 18 000 cal. years before present (Dyke et al., 2003).

Table 1 Previously published regional syntheses of paleovegetational change from northwest North America. This table is limited to papers published since 1990

patterns of individual pollen types, Brubaker et al. (2005) concluded that the common tree and shrub taxa in the Alaskan pollen records survived the last LGM in eastern Beringia. This includes *Picea* (spruce), a dominant taxon in the modern boreal forests, as evidenced by the fact that trace amounts of spruce pollen are common in the LGM sediments from a number of sites. This hypothesis cannot be tested rigorously using fossil data; spruce macrofossils dated to the LGM have not been found. However, a recent analysis of chloroplast DNA in extant trees revealed unique haplotypes and a higher diversity of haplotypes in Alaska than areas farther south (Anderson

et al., 2006), offering unambiguous evidence that spruce did survive the LGM in Alaska. Together, the DNA and pollen data suggest that tundra prevailed on the regional landscape during the LGM, but small populations of trees existed in isolated sheltered areas.

Transition from the Pleistocene to the Holocene

Between 15 and 12 ka, pollen records indicate that herb tundra transitioned to shrub tundra dominated by *Betula* (birch) in response to increases in temperature and effective moisture. *Betula*, *Salix* (willow), and *Cyperaceae* became the dominant taxa, and tundra vegetation cover became more continuous than previously. Associated with these vegetational changes are the stabilization of eolian dunes, aggradation of streams, and formation of organic peat deposits (Mann et al., 2002). A number of pollen diagrams from Alaska display prominent peaks of *Populus balsamifera*, suggesting that this species formed woodlands in at least some local habitats (Figure 2). A recent synthesis of the regional pollen diagrams shows a cluster of *Populus* peaks between 13 and 10 ka (Edwards et al., 2005). These are thought to be evidence of warmer-than-present climatic conditions during the early Holocene, presumably in response to peak values of summer insolation (Kaufman et al., 2004). This age range likely reflects that many of the pollen diagrams are based on bulk-sediment ¹⁴C dating, which tends to yield anomalously old dates. Several recent pollen records with AMS-¹⁴C ages on terrestrial plant macrofossils suggest that the *Populus* interval was post-Younger Dryas. Furthermore, *Populus* peaks occurred at different times at different sites, and midge-based temperature reconstructions from three sites in interior Alaska provide compelling evidence

that the early Holocene was not warmer, probably as a result of ocean–atmosphere–land interactions associated with the states of the Arctic Oscillation and El Niño Southern Oscillation (Clegg et al., 2011).

Pollen records from Alaska indicate that climate cooling during the Younger Dryas Chronozone (YDC; 12.9–11.6 ka) altered the species composition and decreased the cover of terrestrial vegetation in at least some areas of Alaska. Evidence includes decreased tree cover in southeastern Alaska (Engstrom et al., 1990) and the expansion of herb taxa at the expense of *Betula* shrubs in south-central and southwestern Alaska (Hu et al., 1995, 2002; Peteet and Mann, 1994). In northern Alaska, Mann et al. (2002) report a contraction in the range of *Populus balsamifera*, presumably in response to a return to cold and dry conditions. Other evidence supporting YDC-related climatic fluctuations in Alaska includes high-resolution analysis of biogenic silica (diatom remains) in lake sediments (Hu et al., 2002, 2006; Kaufman et al., 2010), geomorphic and paleoecological records of stream down-cutting, eolian dune activity, and reduced peat formation (Mann et al., 2002), and glacier fluctuations (Briner et al., 2002).

The Holocene

Pollen records from several sites with high-quality chronological control indicate the early Holocene expansion of *Populus balsamifera*. This expansion may have resulted from climatic warming and/or from the presence of extensive disturbed mineral soils during the early postglacial interval (Hu et al., 1993). In interior Alaska, *Betula* tree species such as *Betula neoalaskana*, a common component of early-successional stands on the modern landscape, may have also gained importance at this time. Although studies of modern pollen samples indicate that separation of *B. neoalaskana* pollen from shrub-*Betula* species is possible (Clegg et al., 2005; Edwards et al., 1991), few fossil-pollen studies have attempted to distinguish these species in Alaska (Brubaker et al., 1983; Tinner et al., 2008). However, existing pollen and macrofossil records of tree-*Betula* seeds reveal local presence no later than 9 ka (Hu et al., 1993; Tinner et al., 2006).

Pollen assemblages with a substantial amount of *Picea* began to occur as early as 10 ka in the eastern and southern Alaska (Figure 2). The first spruce species to expand in the early Holocene pollen assemblages is *Picea glauca* (white spruce), which probably formed woodland with tree birch between 10 and 9 ka in interior Alaska. Pollen profiles that separate *Picea* pollen to the species level indicate that both *P. glauca* and *P. mariana*, the two common species of today's Alaskan boreal forests, were both present on the landscape by 9 ka in eastern Alaska (Tinner et al., 2006). The expansion of white spruce appears to have occurred from the east to west (Anderson and Brubaker, 1994), and the rates of population increases exhibit major spatiotemporal patterns. In eastern Alaska, *Picea* pollen percentages reached near-modern values within 600 years of initial appearance. Several pollen records from central Alaska display a rise in *Picea* pollen percentages at about the same time as the eastern sites, but the abundance of *Picea* pollen remained substantially below modern abundance until 5 to 6 ka. In central Alaska, boreal forests dominated by *P. mariana*

Figure 2 Schematic diagram showing the spatiotemporal dynamics of postglacial vegetation in Alaska, based on fossil-pollen analysis. Lines indicate the approximate timing of population expansions of select major taxa in the Alaskan pollen records.

similar to those we see today became established around 6.5 ka. Associated with this vegetational change was a pronounced increase in forest fire frequency, which was probably driven by the high flammability of *P. mariana* forests (Higuera et al., 2009; Lynch et al., 2003). Pollen percentages and accumulation rates in lake sediments suggest that the westward migration of sparse *Picea* stands halted around 8 ka, presumably because of an episode of climatic cooling (Hu et al., 1993). *Picea* then resumed its westward expansion to reach its modern western range limit during the late Holocene (Ager and Sims, 1981; Brubaker et al., 1983). A striking spatial pattern based on the dense network of Holocene pollen records from interior Alaska is that in contrast to the rapid spread across the eastern sites, spruce expanded extremely slowly from central to southwestern Alaska, and there is not a clear climatic or ecological explanation for this contrast (Kaltenrieder et al., 2011). As a result of the late expansion of spruce in southwestern Alaska, birch tundra was the prevalent vegetation type for $\geq 10,000$ years, until 3–4 ka when *P. glauca* invaded the region. A recent study showed that the abundance of birch shrubs fluctuated with climatic changes possibly associated with solar-irradiance fluctuations and ocean–atmosphere interactions at hemispheric scales (Hu et al., 2003).

The establishment of spruce forests similar to those of today occurred between 6.5 and 5 ka in interior Alaska (Anderson and Brubaker, 1994). *Picea* pollen percentages began to increase between 6 and 4 ka (Anderson and Brubaker, 1994) near the modern treelines in northwestern Alaska and around 4 ka in southwestern Alaska (Brubaker et al., 2001). Pollen abundance

reached modern values ~2–4 ka, suggesting that the modern forest-tundra ecotone became established during this interval (Anderson and Brubaker, 1994; Brubaker et al., 2001; Hu et al., 1995; Kaltenrieder et al., 2011). Spruce pollen never exceeded 10% of the terrestrial pollen sum during the late Holocene in these regions, suggesting that population densities have never been higher after the development of the modern tundra-forest ecotone in western Alaska. However, this assessment may be a result of the lack of high-temporal-resolution pollen records from western Alaska. The first detailed palynological study of lake sediments of the past 700 years revealed pronounced fluctuations of altitudinal treeline in the Copper River Basin of southeastern Alaska (Tinner et al., 2008). Tinner et al. (2008) conducted multiproxy analyses of lake sediments at decadal-to-centennial timescales to infer ecosystem and climatic fluctuation associated with the Little Ice Age (LIA; ~500–150 years ago). Their pollen data revealed diminished abundance of major tree taxa, including *P. glauca*, *P. mariana*, and *Betula neoalaskana*, as a result of decreases in temperature and effective moisture during the LIA. These changes were accompanied by the expansions of shrub and herbaceous species, including *Alnus viridis*, *Betula glandulosa/nana*, and *Epilobium*.

Alnus (alder) is a major taxon in the many Holocene pollen diagrams from Alaska, reaching 70–80% of the pollen spectra at some sites. The earliest expansion of alder occurred at sites in the northwestern Brooks Range around 9500 years ago, and alder appears to have expanded southward and eastward in interior Alaska. It became a major component of the pollen diagrams at many sites around 8000 cal BP, suggesting the rapid expansion of this taxon across of the landscape around this time. Because alder is a nitrogen fixer, its Holocene expansion probably markedly increased nitrogen availability and accelerated the rate of nitrogen cycling in Alaska, especially where alder is a prevalent component of the terrestrial plant communities such as southwestern Alaska. The N effects of the Holocene alder expansion have been documented with the analyses of lake sediments for biogenic silica, C/N ratio, and nitrogen and carbon isotopes (Hu et al., 2001), although it remains unknown how the increased N availability affected other species that are associated with alder.

In the pollen records from the North Slope of Alaska, *Picea* and *Alnus* are present in the Holocene sediments, but the abundance is low for both taxa. Spruce trees have never been locally present in this region based on the late Quaternary fossil records, and the presence of spruce in the pollen diagrams from the North Slope represents long-distance transport from areas south of the Brooks Range. In contrast, *Alnus* expanded in the Brooks Range and southern Arctic Foothills between 8 and 7 ka (Bergstrom, 1984; Eisner, 1991; Livingstone, 1955; Oswald et al., 1999, 2003). Tundra communities similar to those of today became established during the early–middle Holocene (Oswald et al., 1999, 2003). A detailed palynological study (Oswald et al., 2003) demonstrated that the trajectories of Holocene vegetation development differed between two major geomorphic substrates related to the Quaternary glacial history of the region. On the Sagavanirktok surface (>500,000 years old), relatively dry and sparse tundra dominated by prostrate shrubs transitioned to tussock tundra dominated by *Betula nana*,

Eriophorum vaginatum, Ericaceae species, and *Sphagnum* mosses (Walker et al., 1994) around 7500 years ago. In contrast, at a nearby site on the Itkillik II surface (~14,000 years old), pollen analysis revealed that prostrate-shrub tundra communities prevailed on the landscape since the early Holocene, although vegetation cover may have increased around 7500 years ago (Oswald et al., 2003). Oswald et al. attributed this vegetation-history contrast to differences in soil texture and geomorphology between the two geomorphic surfaces. Specifically, as effective moisture increased from early to middle Holocene, the fine-texture soils and gentle topography of the older Sagavanirktok surface promoted buildup of soil organic matter, shallowing of permafrost table, and development of water-logged soils, which would have favored the development of tussock tundra. These changes probably did not occur on the younger Itkillik II surface because of better drainage associated with coarser-texture and less-acidic soils.

Marine West Coast Forest

Last Glacial Maximum

A 7.7-m peat core from coastal western Washington, located south of the maximum extent of the Juan de Fuca lobe of the Cordilleran ice sheet, revealed a coarse vegetation history that may extend to the previous interglacial (Heusser et al., 1999). The full-glacial pollen assemblages are comprised mainly of *Pinus* (pine, mainly the shore-pine variant of *P. contorta*), *Tsuga mertensiana* (mountain hemlock), and Poaceae, suggesting cold open parkland, in contrast to dense *Picea sitchensis* (Sitka spruce)/*T. heterophylla* (western hemlock) at the site today. Similar pollen assemblages, but with more warm-adapted *T. heterophylla* pollen, were found in the low elevations of the coastal ranges of western Oregon and southwest Washington (Grigg and Whitlock, 2002; Grigg et al., 2001). In the unglaciated western Cascade Range of central Oregon, a debris flow deposit dated to >35 ka contained abundant macrofossils of tree species common today 1000 m higher in elevation, including *Picea engelmannii* (Engelmann spruce) and *Abies lasiocarpa* (subalpine fir). Further to the east, the High Cascades were covered by an ice sheet at the time (Figure 1). Taken together, these records indicate that forest cover occurred within 10s to 100s of kilometers from the ice sheet maximum, that subalpine forest types extended to low elevations, but also that warm-adapted conifer tree species persisted at some sites in Oregon. The most abundant warm-adapted species in the region today, *Pseudotsuga menziesii* (Douglas-fir), was very rare but likely present in Oregon during the last glacial (Gugger and Sugita, 2010).

Ice-free areas existed in certain locations north of the southern ice sheet margin during the LGM. In combination with lower sea level, many headlands along the British Columbia and Alaska coast remained ice-free allowing for persistence of plant and animal populations in refugia. Refugia have been identified on the basis of pollen and macrofossils on the Queen Charlotte Islands, Alexander Archipelago, and Vancouver Island (Carrara et al., 2007; Hebda, 1997; Warner et al., 1982). These findings are supported by phylogeographic studies (reviewed in Shafer et al., 2010) and findings of tree

macrofossils appearing in offshore postglacial sediments near Vancouver Island (Lacourse et al., 2003).

Transition from Pleistocene to Holocene

At 14.5 ka, a rapid warming initiated the retreat of many alpine glaciers, while at the same time, the Cordilleran ice sheet limit was moving northward. In the Oregon Coast Range, this transition involved a change from subalpine parkland to lowland tree species (*Alnus rubra* (red alder) and *Pseudotsuga menziesii*). The abrupt increase of *Pseudotsuga menziesii* is notable, given its rarity or absence during much of the glacial maximum (Grigg and Whitlock, 1998; Worona and Whitlock, 1995). Further north, from Puget Sound northward, the initial colonizer of deglaciated landscapes was almost entirely *Pinus contorta*, followed by a mix of subalpine species (*Abies*, *Picea*, and *Tsuga mertensiana*) between 14 and 13 ka. Here, the transition out of this parkland vegetation occurred later (at 12 to 11 ka) than at sites further south, typically close in time to the first major increase of *Pseudotsuga menziesii* (Cwynar, 1987).

The YDC (12.9–11.6 ka), as recorded by several nonvegetation climate proxies in this region, was a distinct cold and dry interval (Barron et al., 2003; Heine, 1998; Vacco et al., 2005), but its expression in the vegetation record is variable. Pollen records show little change in forests in western Oregon directly associated with the YDC, possibly reflecting the fact that warm-adapted vegetation was well established before the YDC and that many species (e.g., *Pseudotsuga*) have broad climatic tolerances (Grigg and Whitlock, 1998). From Vancouver Island northward, pollen assemblages from coastal sites show subalpine-adapted species (*Tsuga mertensiana*) and low pollen influxes coeval with the YDC (Brown and Hebda, 2002; Lacourse, 2009; Mathewes, 1993).

The Holocene

The early Holocene is marked by increased summer insolation (8% more relative to modern at 50°N) that strengthened the Pacific Subtropical high-pressure system, creating warm stable and dry air in coastal regions. Throughout the Pacific

Figure 3 Pollen zones and inferred fire activity for eight low-elevation sites in the Marine West Coast Forest ecoregion from south (left) to north (right): Little Lake, OR (Long et al., 1998; Worona and Whitlock, 1995), Battle Ground Lake, OR (Barnosky, 1985; Walsh et al., 2008), Mineral Lake and Hall Lake, WA (Sugita and Tsukada, 1982), Kirk Lake, WA (Cwynar, 1987), East Sooke Fen, Pixie Lake, and Whyac Lake, BC (Brown and Hebda, 2002). Reproduced from Walsh MK, Whitlock C, Bartlein PJ (2008) A 14,300-year-long record of fire–vegetation–climate linkages at Battle Ground Lake, southwestern Washington. *Quaternary Research* 70: 251–264.

Northwest, the early Holocene is marked by hotter summers and increased drought and forest fire (Figure 3). Records from insect remain in lake sediments in southern British Columbia quantified July temperatures at 3 °C warmer than present (Gavin et al., 2011), in agreement with a temperature reconstruction based on pollen data from southeast Oregon (Minckley et al., 2007). In western Oregon and Washington, increased fire and summer warmth fostered widespread early-successional *Pseudotsuga*–*Alnus rubra* forests with abundant *Pteridium* spores indicating full-sun conditions after severe forest fires (Brown and Hebda, 2002; Sugimura et al., 2008). There is mounting evidence, however, that the early Holocene was not uniformly warm and dry, but was marked by distinct century-scale intervals of increased moisture. The remnants of the waning ice sheet to the north (which had its last major collapse at 8.5 ka) may have still been influencing the path of the jet stream across western North America (Gavin et al., 2011).

The transition out of the early Holocene was marked by increasing representation of shade-tolerant late-successional species (*Tsuga* and *Abies*), the decline of *Pseudotsuga* and *Alnus rubra*, and a decrease in fire. This transition began as early as 8 ka, but modern pollen assemblages were not reached until some time between 6 and 3 ka. The wide range in timing of the establishment of modern assemblages may be due to progressive development of ecosystem properties that favor acid-tolerating species such as *T. plicata*, a species that arrived comparatively recently north of Vancouver Island (Hebda and Mathewes, 1984). In southeast Alaska, the cooler and wetter climate was marked by several vegetation changes, including the expansion of *Tsuga* and development of paludified soils (Hansen and Engstrom, 1996). One reversal (warming) in the Neoglacial cooling trend was a period of increased fire found at several sites in British Columbia and Washington, beginning at 2.5 ka and possibly attributable to human-set fires (Hallett et al., 2003; Prichard et al., 2009; Sugimura et al., 2008).

Western Cordillera

Last Glacial Maximum

Few sediment records extend to the glacial maximum in the unglaciated terrain of eastern Washington and Oregon (Bartlein et al., 2010). In the rain shadow of the Cascade Range, near the modern forest–steppe boundary, the LGM vegetation was dominated by *Artemisia*, Poaceae, and herb taxa (Whitlock et al., 2000). Modeling of paleoclimate and species distributions over western North America for the glacial maximum is consistent with the inferences from the few existing geologic records: contraction of warm-adapted conifers (e.g., *Pseudotsuga*) and expansion of cold-adapted *Picea* and *Artemisia* (Bartlein et al., 1998).

Transition from Pleistocene to Holocene

Most of the Cordilleran ice sheet persisted in valley bottoms until the Holocene; therefore, few pollen records in inland British Columbia encompass the late Pleistocene. East of the Cascade Range, *Artemisia* and *Pinus* dominated the pollen assemblages, indicating a more open and drier vegetation type than occurs today. At Waitts Lake in northeastern Washington,

increased *Artemisia* coincided with the YDC, though *Artemisia* was already increasing prior to a tephra marker at 13.1 ka (Mack et al., 1978; Walker and Pellatt, 2008). Peak *Artemisia* during the YDC was followed by increased tree (*Pinus* and *Alnus*) pollen until 10.5 ka. Further south in Idaho and western Montana, a *Picea* parkland predominated at higher elevations before 13 ka, which changed to a closed pine forest during the YDC (Brunelle et al., 2005).

The Holocene

Increased warm-adapted taxa occur throughout the Western Cordillera during the early Holocene. At lower elevations, increased Poaceae and decreased tree pollen suggest an uphill retreat of the forest-grassland ecotone (Mack et al., 1978). In the mountains of central Idaho and western Montana, cool-adapted conifers (*Picea* and *Abies*) declined with increased *Pseudotsuga*/*Larix* pollen from 11.5 to 7.5 ka (Brunelle et al., 2005). In British Columbia, recently deglaciated land was usually colonized by *Pinus* cf. *contorta*, though pollen records indicate a fairly rapid primary succession to a more diverse forest (Gavin et al., 2011). Modern forest conditions generally developed by 4 ka with an increase in mesic taxa, such as *Picea* and *Abies* in subalpine forest sites.

An event during the early Holocene that deserves special mention is the eruption of Mount Mazama that created Crater Lake 7627 ± 150 years ago (Zdanowicz et al., 1999). The ash deposits from this eruption blanketed the northwest, especially east of the Cascade Range. This ash layer created the seed bed for today's forests and altered the trajectories of forest change. In some areas, extremely thick ash deposits led to 'tephra plains' that remain very dry and sparsely vegetated today. In other areas, ash deposits thickened soils and may have allowed for greater water retention. Colonization of forest on steep coarse rock talus in the mountains may have required the addition of tephra to function as a mulch and thus changed the character of the steeper parts of the landscapes (Mehring et al., 1977).

In wetter subzones of the Western Cordillera, forests contain many species disjunct from their main coastal distribution. Originally hypothesized to be the result of a Miocene vicariance (following Cascadian orogeny), this biogeographic pattern and its potential root in a northern Idaho refugium have received much focus from geneticists and paleoecologists (Carstens et al., 2005; Daubenmire, 1968). The emerging picture is that each species has a unique history, that many plant species dispersed during the Holocene from the coast, and that the modern mesic-forest composition in northern Idaho may be a very recent feature of the landscape (Gavin, 2009; Gavin and Hu, 2006; O'Connell et al., 2008; Shafer et al., 2010). Further north within the belt of mesic forests, the earliest detection of the modern forest dominant (*T. heterophylla*) occurred at 4.5 ka, coincident with the decline of *Betula* and transition from a continental to a cool and wet maritime climate (Gavin et al., 2011).

In the Western Cordillera, forests dominated by pine and mixed conifers support a complex mixed-severity fire regime. Vegetation and fire histories are of great importance for land managers who are setting restoration targets based on the historical range of variation in vegetation and disturbance

rates. Pollen and charcoal records from the Western Cordillera are summarized in several papers (Gavin et al., 2007; Marlon et al., 2009; Whitlock et al., 2008). Fires are a long-term presence from wet coastal forests to dry interior basins, and the Holocene vegetation history is more precisely interpreted alongside independent fire-history data. Some especially high-resolution studies have demonstrated a highly episodic history of fire, showing that any reference to disturbance regimes from the past 300 years alone does not describe the degree of variability that occurs over longer periods, including events of high severity and low frequency that may be considered highly undesirable today (Colombaroli and Gavin, 2010). Over the entire Holocene, the regional coherence of paleorecords indicates that increased fire during the early Holocene thermal maximum promoted disturbance-adapted vegetation. There is some evidence that east of the continental divide increased insolation resulted in increased summer moisture, more mesic vegetation, and reduced fire (Whitlock et al., 2008).

Cold Deserts

In general, the pollen assemblages from this region are dominated by broadly dispersed and highly productive pollen taxa. Thus, pollen records from these regions reflect broad areas. In addition, these drought-adapted taxa have wide ecological amplitudes, resulting in more stable populations through short-term climate change. However, the vegetation changes that are detected in these regions are concordant with the paleoclimatic inferences from the coastal region. For example, a well-studied core from Bear Lake confirms the increased extent of cold- and dry-adapted steppe taxa during glacial maxima (Jimenez-Moreno et al., 2007).

Pollen data from eastern Oregon and Washington indicate less dense vegetation than present at 14 ka (Mehring, 1996; Minckley et al., 2007). The pollen assemblages from the cold deserts show little sensitivity to the YDC, though all sites show increased herb taxa after 11 ka, indicating warmer and drier conditions. Decreased fire at this time likely reflects reduced biomass continuity (Minckley et al., 2007). After 7 ka, *Pinus* forest increased at high elevation sites and modern pollen assemblages were reached at most sites shortly thereafter.

Conclusions

The vegetation history of NWA is becoming more fully understood due to a large number of recent studies. The region is poised to provide information on postglacial vegetation dynamics similar to that available from eastern North America. Maps of taxa and community types through the late Quaternary may soon be possible in this region. This rich data set will further our understanding of the millennial-scale controls of vegetation change, while high-resolution pollen analysis has begun to reveal coherent decadal-to-century-scale changes. These latter efforts provide important information on ecological responses to rapid climate change.

The paleoecological record from the Cordillera provides an example of how populations persist on the landscape through periods of rapid climate change and how combinations of climate change and natural disturbances may rapidly

transform entire ecosystems. The existence of pockets of endemism today suggests a long-term history of isolation and persistence. Applying both genetic and fossil investigations into the history of patterns of disjunction and endemism is a powerful biogeographic approach to understand the origin of modern patterns of diversity. There remains much potential by merging these lines of evidence in the study of vegetation in the Pacific Northwest.

The paleoecological record can also inform managers in setting restoration target points. Large areas of dry forest in the Pacific Northwest have 'missed' several cycles of fire since the period of effective fire suppression. Disagreement on the character of the historical range of variability of fire frequency and fire severity exists despite decades of research on the topic. The sediment record, where it is of sufficiently high resolution, is a powerful tool to describe the historical range of variability in natural disturbances and its link to climate change.

Introduction

The southeastern United States has a diverse flora and fauna that reflects the topographic and latitudinal gradients characterizing the region. This region ranges from Virginia and Tennessee in the north to the Gulf of Mexico in the south and is bounded on the west by the Mississippi River and the east by the Atlantic Ocean. It was south of the maximum extent of continental ice during the Last Glacial Maximum (LGM) (21.5 ± 1.5 cal ka BP) (Jackson et al., 2000; Figure 1). As such, the southeastern United States served as a refugium for plant and animal species that migrated south during the last glaciation. Postglacial sedimentary records provide details on migration rates and environmental tolerances of taxa during the interval ranging from the LGM to the present day. This article summarizes more than 75 years of research on the vegetational history of the southeastern United States and highlights current and potential future directions for paleoecological research in the region.

Initial research on southeastern United States floras began in the 1930s, with studies of pollen records from peat bogs by Sears (1935). Although chronologic control was poor before the advent of radiocarbon dating in 1950, these researchers developed a fundamental understanding of the history and development of the southeastern flora through studies of pollen from lake and bog sediments. After 1950, radiocarbon dating facilitated analysis of the timing of millennial-scale events associated with the last glaciation and the response of southeastern United States vegetation to climatic amelioration of the deglacial and Holocene intervals. Basic biogeographic questions were researched throughout the region by Braun (1950), Whitehead (1965), Watts (1979), Delcourt and Delcourt (1984), and others in a series of site studies of lakes and wetlands. Since the 1980s, the ability to date very small samples with ^{14}C accelerator mass spectroscopy, to undertake quantitative paleoecological analyses, and to integrate paleoecological results with climate models has enabled more sophisticated analyses of broad climatic impacts and patterns of late Quaternary vegetational change (Jackson et al., 2000; Webb et al., 1998). Recent attention has focused on the following: (1) development of pollen records with greater temporal resolution to evaluate the timing of forest response to decadal- to -centennial-scale climate fluctuations and (2) improved calibration of pollen assemblages with environmental parameters including temperature and hydrology (Sugita, 2007; Whitmore et al., 2005; Willard et al., 2011). Improved geochronology is allowing more direct comparison of pollen records with ice core and marine sediment records, improving regional and extraregional reconstructions of vegetation and changes in air temperature and precipitation. In the following sections, the modern distribution of vegetation and pollen is discussed, followed by a discussion of patterns of change in plant communities from the LGM into the present interglacial interval.

Modern Forest Distribution and Composition in the Southeastern United States

The diverse vegetation of the southeastern United States reflects the complex topography and physiography of the region (Figure 2(a)). Both the Atlantic and Gulf coastal plains are dominant elements of southeastern United States, characterized by low topographic relief. The Atlantic coastal plain extends southward from New Jersey to Florida, grading westward into the Gulf coastal plain and extending as far north as southern Illinois at the head of the Mississippi embayment (Figure 2(a)). The western margin of the Atlantic coastal plain is clearly defined by the fall line, the boundary between the upland Piedmont province and Atlantic coastal plain that marks a mid-Pliocene highstand of sea level. The Piedmont, Blue Ridge, Ridge and Valley, and Appalachian plateau provinces are more topographically diverse, including fold belts with significant relief and relatively flat plateaus with minimal relief. Coupling the extreme local variability in topography and substrate with climatic gradients related both to latitude and altitude, these regions encompass great diversity in forest composition (Figure 2(b)).

Vegetational associations in the southeastern United States include the wetlands and tropical vegetation of south Florida, southeastern evergreen forests, oak-pine forests, and a series of deciduous forests including the Appalachian oak/oak-chestnut forests, mixed mesophytic forests, and western mesophytic forests (Figure 2(b); Braun, 1950; Kuchler, 1964; Greller, 1988). The southern one-third of the Florida peninsula consists of extensive wetlands, including freshwater marshes and forested wetlands of the Florida Everglades and saline-influenced coastal marshes and mangrove forests along Florida Bay and the Gulf of Mexico. The freshwater marsh communities of the Everglades ecosystem consist primarily of saw grass marshes and water lily sloughs with tree islands interspersed throughout the system (Willard et al., 2001). These communities occur primarily on a peat substrate, and the community composition is determined by hydroperiod (annual period of inundation), water depth, and fire regime.

Forested wetlands of the Atlantic and Gulf coastal plains include Everglades tree islands, coastal mangrove swamps, and floodplains of coastal plain rivers. The latter have acted as sediment sinks during the Holocene, and lateral accretion of sediment during flood events has influenced the structure of floodplain environments, with coarse-grained sediments deposited on levees and finer-grained sediments deposited in backswamps distal to the stream. The hydrologic, topographic, and geomorphic diversity (substrate elevation, distance from river mouth, soil texture, and organic matter content) inherent to coastal plain floodplains determines the structure of floodplain vegetation (Rice and Peet, 1997; Townsend, 2001). Floodplain forests include cypress and tupelo (*Nyssa*) in backswamps that are flooded for prolonged periods of time

Figure 1 Map of southeastern United States with location of sites discussed within the text. Site numbers are keyed to localities in [Table 1](#). Shaded area shows maximum extent of continental ice sheet during Last Glacial Maximum.

(pocosin vegetation of [Figure 2\(b\)](#)) and hardwood assemblages (oak, sweet gum, ash (*Fraxinus*)) on the better-drained levees ([Hupp, 2000](#)).

The remainder of the Florida peninsula and southern Mississippi, Alabama, Georgia, and the eastern Carolinas are occupied by southeastern evergreen forests. This vegetation association occupies the Atlantic and Gulf coastal plain provinces and is dominated by longleaf pine (*Pinus palustris*) and broad-leaved evergreens such as live oak (*Quercus virginiana*). Longleaf pine forests occupy xeric sites and consist of an overstory of longleaf pine, an understory of oaks, and an herbaceous layer consisting primarily of grasses ([Braun, 1950](#)). Deciduous taxa are more common in the northern reaches of the association, where loblolly pine (*P. taeda*) forests include a number of hardwoods (oak, *Quercus*; hickory, *Carya*; sweet gum, *Liquidambar*; and maple, *Acer*).

The oak–pine association lies north of the southeastern evergreen forests, extending southward from southern New Jersey to Georgia and westward to the Mississippi River ([Figure 2\(b\)](#)). It encompasses part of the Piedmont plateau along the Atlantic coast and the Piedmont, Valley and Ridge,

Figure 2 (a) Physiographic regions of southeastern United States, (b) Forest associations of the southeastern United States. Adapted from Braun LE (1950) *Deciduous Forests of Eastern North America*. Philadelphia: The Blakiston Company; K  chler AW (1964) *Potential Natural Vegetation of the Conterminous United States*. New York: American Geographical Society. Special Publication No.36, pp.1–116; Greller A (1988) Deciduous forest. In: Barbour MG and Billings WD (eds.) *North American Terrestrial Vegetation*, pp. 287–316. Cambridge: Cambridge University Press.

and Appalachian plateau along the Gulf coast. Although deciduous hardwoods are the dominant elements of these forests, pines are a consistent member of the association, thus distinguishing it from the oak–hickory region to the north (Braun, 1950). Oak dominates forests of the oak–pine association, and pine, hickory, and various hardwoods are subdominant (Braun, 1950). North of the Gulf coastal plain, the oak–pine association is a transitional zone with considerable overlap in ranges of trees from the mixed mesophytic forests to the north and evergreens to the south. Longleaf pine is a common component in southern reaches of this association, along with *Magnolia*, oak, hickory, and *Castanea* (chestnut). In higher elevations, beech (*Fagus*), sweet gum, maple, and other mesophytic taxa are common. The James River in Virginia represents the northern boundary of this association; north of the river, longleaf pine, and live oak are minor forest components.

A series of deciduous forests lie north of the oak–pine association and include the oak–chestnut, mixed mesophytic, and western mesophytic associations described by Braun (1950). These forests cover much of the unglaciated Appalachian plateau, the southern Appalachian Mountains, and part of the Piedmont plateau (Figure 2(a) and 2(b)). These associations are dominated by hardwoods (oak, hickory, maple, tuliptree (*Liriodendron*), hemlock (*Tsuga*), basswood (*Tilia*)), and species dominance is determined primarily by site characteristics. On the Appalachian plateau, oak, hickory, maple, and beech are the primary taxa. The Piedmont plateau is characterized by a rich mix of oaks and hickories, and loblolly pine (*Pinus taeda*) and shortleaf pine (*P. echinata*) are common in secondary forests. In the southern Appalachian Mountains, there is a gradient from diverse stands of hardwoods at low elevations to forests with spruce (*Picea*), fir (*Abies*), and eastern white pine (*Pinus strobus*) at high elevation (Braun, 1950).

Pollen Signature of Modern Vegetation

Calibration of the pollen record with modern vegetation in the southeastern United States has been undertaken in a comprehensive fashion (Delcourt et al., 1984; Webb et al., 1993). These synoptic views, focused primarily on lake records, provide a regional synthesis of surrounding vegetation. More recently, a number of studies examined pollen–vegetation relationships in wetlands. These studies documented more local-scale variation in order to examine impacts of local sedimentation, hydrology, and land cover change (Willard et al., 2001, 2005, 2011). Below, the general patterns of pollen distribution in the southeastern United States are summarized for key taxa within the region.

Pines of the southeastern United States include species whose ranges are limited by soil characteristics, moisture availability, and winter temperature (Iverson et al., 1999; Thompson et al., 2000). Southeastern pines are most common on sandy coastal plain sediments and decrease in abundance northward to a minimum in oak–chestnut forests of the mid-Atlantic. Although pine tends to be overrepresented in pollen records, this is paralleled by its abundance in forests (Delcourt and Delcourt, 1984). Where pines are rare in the watershed, their pollen is similarly uncommon in sediments. Recent analysis of pine pollen abundance in estuarine and shallow marine sediments clearly documents the positive relationship between pine pollen abundance and abundance in adjacent forests, as well as the correlation between abundance of southeastern pine pollen with both latitude and winter temperature (Willard et al., 2005).

Oak and hickory encompass numerous species with broad ecological ranges. Oak is most abundant on the Cumberland plateau of Tennessee and Alabama, in the Ridge and Valley and Blue Ridge provinces, decreasing southward as the association grades into more conifer-rich forests (Delcourt and Delcourt,

1984). Hickory is most abundant in the interior lowlands of Tennessee and Kentucky and is rare on the coastal plain (Delcourt and Delcourt, 1984; Iverson et al., 1999). Its pollen abundance closely parallels its distribution in forests, providing a reliable proxy for its presence and abundance in the pollen record. Within both genera, it is difficult to distinguish between species based on pollen morphology because size and subtle morphological differences between species may vary among reference collections. In a few cases, however, size can be used to differentiate species. For example, *Carya floridana*, a species restricted to Florida, is significantly smaller than other *Carya* species that have a more temperate/northern distribution (Whitehead, 1965). Such difficulties in distinguishing hickory or oak species in the pollen record make identification of particular edaphic or topographic characteristics based on species identification of pollen problematic.

Spruce, fir, and eastern white pine are common elements in the northern hardwoods and boreal forest regions and also occur rarely at high elevations in the central Appalachian Mountains of the southeastern United States. Hemlock and beech also are restricted to mid- to high elevations of the Appalachians (Delcourt and Delcourt, 1984). Other species with restricted distribution include those characteristic of backswamps of coastal plain rivers and other swamp complexes, including tupelo, cypress, and *Salix* (willow). Tupelo and willow pollen are found most commonly in backswamp sediments, with poor representation in adjacent levee deposits (Willard et al., 2011). Cypress pollen is restricted to sediments deposited in cypress swamps (Willard et al., 2001, 2011). Although its pollen is difficult to distinguish from that of the Cupressaceae (including the cedars *Juniperus* and *Chamaecyparis*), the latter occur on drier, shallow, upland soils, and the accompanying taxa in the upland associations differ completely from those of alluvial backswamps.

Quaternary Palynological Records from Lakes, Estuaries, and Wetlands of the Southeastern United States

The unglaciated southeastern United States is an excellent region to examine vegetational response to retreat of the Laurentide Ice Sheet and associated climatic fluctuations during the last ~22,500 years. The combined analysis of lacustrine, estuarine, and wetland deposits over the past few decades has enriched our interpretation of regional response to climate fluctuations on differing scales. Lacustrine sediments have been used extensively to interpret the vegetational history of the region because they contain long-term, relatively continuous records of sediment deposition. Lake deposits have been studied intensively throughout the region, including karst lakes of the Florida peninsula, sinkhole lakes throughout the Appalachians, and 'Carolina bays' along the Atlantic coast. Many of these lakes contain records covering at least the last 20,000 years with varying degrees of temporal resolution due to both varying sedimentation rates and density of analysis. Recent analyses have included estuarine records with high sedimentation rates that provide decadal- to -centennial-scale temporal resolution, as well as wetland records from marshes and forested wetlands (Willard et al., 2001, 2011; Willard et al., 2007).

Estuarine sediments preserve a record of regional forest composition and have the potential for extremely high pre-Colonial sedimentation rates (up to 1 cm/decade at some sites in Chesapeake Bay; Willard et al., 2005). Estuarine pollen records may be integrated with interpretation of past water quality conditions (temperature, oxygen content, turbidity) from floral, faunal, and geochemical proxies (Cronin et al., 2003; Willard et al., 2003), providing a crucial link between terrestrial and estuarine processes and a means to evaluate the impact of post-Colonial land use activities on the watershed, tributaries, and estuary.

Because of their sensitivity to relatively subtle changes in climate and hydrology and the generally excellent preservation of pollen, wetland records provide a unique perspective on wetland distribution and extent over long time intervals. Marsh records may provide sufficient temporal resolution to document the response of wetland communities to late Holocene climate fluctuations. These records provide particularly good evidence for impacts of land use change since European colonization, including altered sedimentation rate and type, plant community shifts, and interpretations of relative differences in pre- and post-Colonial hydrology.

LGM (22.5–19.5 cal ka BP)

Sedimentary records of the LGM are preserved in lakes, wetlands, and ponds throughout the southeastern United States as well as in outcrops. Well-developed chronologies for these sections are difficult to establish because of low deposition rates, sedimentary hiatuses, and radiocarbon dating issues related to carbon source, root intrusion, and carbon content of sediments (Jackson et al., 2000). To evaluate the paleoenvironmental history of the LGM in the southeastern United States, Jackson et al. (2000) incorporated 9 of the 18 sites used in the Cooperative Holocene Mapping Project (COHMAP) pollen database (Webb et al., 1993, 1998) with more recently reported sites to maximize the chronological accuracy of their LGM reconstruction. Sites with low sedimentation rates during the LGM period were excluded; for sites with variable sedimentation rates, only samples closely associated with LGM age dates were included to provide a snapshot of vegetation during the interval. All radiocarbon dates presented here have been calibrated to calendar years and are presented as calendar kiloyears before present (cal ka BP).

During the LGM, taiga, steppe, and boreal forest occupied sites near the ice margin, and the southern limit of the boreal forest region was up to 1200 km south of its present limit in Canada (Delcourt and Delcourt, 1985). Alpine tundra has been documented in LGM sediments near the ice margin in Pennsylvania and mid-elevations in the central Appalachians of West Virginia (Watts, 1979), whereas taiga appears to have been limited to western localities near the ice margin (Jackson et al., 2000). Boreal forests, characterized by abundant spruce throughout most of their range, extended southward from near the ice margin into Georgia and Alabama (Jackson et al., 2000). Fir was concentrated in a narrow band along the southern limit of the forest where moisture is thought to have been more abundant during the growing season (Delcourt and Delcourt, 1985). Mixed conifer/deciduous forests dominated the Atlantic coastal plain, with northern hardwoods present in

the Carolinas and southern pines more abundant in Georgia and northern Florida (Jackson et al., 2000). Hickory and sweetgum were common elements of LGM forests as far south as Tampa Bay (Jackson et al., 2000; Willard et al., 2007).

Deglacial Interval (19.5–10 cal ka BP)

Sites throughout the southeastern United States exhibited significant changes in forest composition around 17 cal ka BP, although sites near the northern limit of the full-glacial boreal forest responded as early as 19 cal ka BP (Delcourt and Delcourt, 1984). Significant decreases in abundance of northern pines and spruce from Florida to Virginia and Tennessee are accompanied by greater abundance of pollen of more mesic and cool-temperate deciduous taxa after ~17 cal ka BP (Figure 3). The decreased abundance of spruce pollen after ~17 cal ka BP indicates a northward shift of their populations after the glacial maximum, but spruce and fir pollen remained common throughout the deglacial interval in both Virginia and Tennessee. The incorporation of rare mesic species with boreal species into a mixed conifer deciduous forest is interpreted to represent the continuation of relatively cool climatic conditions during an interval with greater summer precipitation than the full glacial. In southern sites (Florida, South Carolina), the common occurrence of pollen of temperate hickory species indicates a southward persistence of its population center during the early deglacial.

A second vegetational shift occurred ~15 cal ka BP at most southeastern sites, with the intensity and timing of this change varying latitudinally. In northern and central Florida, hickory abundance decreased and pine abundance increased after 15 cal ka BP, most likely reflecting greater abundance of southern pines such as shortleaf and loblolly pine. At White Pond in South Carolina, hickory, oak, beech, and hop hornbeam pollen abundance increased after 15 cal ka BP. These patterns are mirrored throughout the region (Figure 3) and represent the expansion of mesic trees into the mid-latitudes of the southeastern United States as climatic conditions ameliorated (Delcourt and Delcourt, 1985). These deglacial forests differ distinctly from midlatitude forests of the Holocene in both species composition and dominance. Hemlock and eastern white pine (*P. strobus*) occurred south of their modern distribution, and cypress occurred much farther inland than its present coastal limits. Although few sites have sufficient temporal resolution to evaluate vegetational response to centennial-scale events such as the Younger Dryas, there are indications of significant forest changes at Cahaba Pond, AL, where beech disappeared and pine/oak increased (Figure 4). Likewise, variability in abundance of pine, oak, and Amaranthaceae (pigweed) pollen in lake sediments from Florida indicates forest response to altered hydrology throughout this interval, although clarification of the timing of specific vegetational events is needed (Grimm et al., 2006; Willard et al., 2007). Although records from the high-altitude Browns Pond in the Virginia Appalachians indicate warmer conditions during the Younger Dryas (Kneller and Peteet, 1999), Chesapeake Bay pollen records indicate cooler drier conditions on the coast (Willard et al., 2010). Additional records with high temporal resolution and robust chronologies are needed to improve our understanding of the response of

regional vegetation to deglacial climatic events including the Bölling-Allerød and Younger Dryas.

Early Holocene (10–5 cal ka BP)

Early Holocene forests of the southeastern United States typically were oak–pine forests with decreased representation of mesic trees relative to the late deglacial interval. In Florida, high percentage of oak, Asteraceae (aster) and Poaceae (grass) pollen in early Holocene sediments indicates the presence of closed oak scrub forest with widespread areas of prairielike vegetation (Watts and Hansen, 1994). Pollen assemblages from Cahaba Pond in Alabama were dominated by oak whereas common nonarboreal pollen, mesic, and hydric taxa were relatively rare, and species richness was low, prompting interpretations of increased evapotranspiration stress and decreased precipitation (Delcourt et al., 1983). Hydrologic variability also was documented in assemblages from Dismal Swamp, North Carolina, where oak and hickory dominate early Holocene assemblages (Figure 4). Fluctuating abundance of herbaceous and aquatic taxa in this site are interpreted as recording local fluctuations in precipitation and the water table (Whitehead, 1972). Oak–chestnut forests dominated early Holocene forests of the Virginia mountains and Chesapeake Bay region, and periodic cooling, including the 8 cal ka BP event, is documented by increased montane conifers and decreased pine pollen abundance, respectively (Grimm et al., 2006; Willard et al., 2005). Dominance of oak, decreased abundance of hop hornbeam, spruce, and mesic species and increased abundance of trees around the pond all indicate drier conditions with lower, seasonally fluctuating water levels at Jackson Pond, Kentucky (Wilkins et al., 1991). The record from Anderson Pond in central Tennessee stands in contrast to other sites, demonstrating the continued common occurrence of mesic species throughout the early Holocene (Delcourt, 1979). The earliest documented occurrence of tupelo–cypress backswamps along Atlantic coastal plain rivers ranges from ~9 to 6 cal ka BP in Georgia and North Carolina (Goman and Leigh, 2004; LaMoreaux et al., 2009), near abandoned channel deposits. Although the high abundance of tupelo pollen indicates locally long hydroperiods related to fluvial processes, these complete pollen assemblages are characterized by greater early Holocene abundance of oak pollen relative to pine, indicating a regionally dry climate.

Late Holocene (5 cal ka BP to Present)

After ~5 cal ka BP, insolation changes caused cooler summers and warmer winters of the neoglaciation, resulting in substantial changes in forest composition throughout the southeastern United States. The most striking change was a widespread increase in pine abundance throughout the entire Atlantic coastal plain from Florida peninsula to New Jersey (Watts, 1979). Based on the modern distribution of pine species, this represents a northward expansion of the southern pines (shortleaf, slash, longleaf, and loblolly pine), which require relatively warm winters ($\geq 0.6^\circ\text{C}$), high moisture availability ($>885\text{-mm}$ annual precipitation), and unconsolidated soils (Iverson et al., 1999; Thompson et al., 2000). The shift from oak to pine dominance in these coastal plain sites suggests a

Figure 3 Pollen records of full glacial through deglacial age in the southeastern United States. Points on map indicate sites with information relevant to reconstructions discussed in text. replacement of early Holocene oak–hickory-dominated forests by northerly expanding southeastern evergreen forests up to the southern Chesapeake Bay watershed. Spruce and fir locally expanded their populations into mid- and high elevations in the central and southern Appalachian Mountains (Delcourt and Delcourt, 1985), and chestnut expanded northward to help form extensive oak–chestnut forests. Local changes in hydrology and sedimentation resulted in development of swamp forests in the coastal plain (such as Dismal Swamp, North Carolina), around the Carolina Bays, and around coastal plain ponds (e.g., Cahaba Pond, Alabama). Although isolated tupelo–cypress swamps have been identified from early Holocene sediments (Goman and Leigh, 2004; LaMoreaux et al., 2009), most of the existing swamp forests originated in the late Holocene (Whitehead, 1972). Recent evidence from a 2500-year record from Roanoke River backswamp documents substantial hydrologic variability over centennial scales (Willard et al., 2011), but an improved chronology is necessary to correlate it with specific climate events.

High-resolution records from Chesapeake Bay document a forest response to quasiperiodic cool intervals superimposed upon the entire Holocene record (Willard et al., 2005). These consist of periodic decreases in pine abundance every ~1500 years that correlate with intervals of increased ice rafting in the North Atlantic Ocean and solar minima interpreted from ice core records. Although this remains to be substantiated in other sites with high temporal resolution, it suggests that forests of the southeastern United States were capable of responding to centennial-scale climate events in a manner recognizable in the sedimentary pollen record.

Implications for Future Research

Postglacial records of southeastern United States vegetation continue to provide valuable reconstructions of biogeographic trends and paleoclimatic interpretations of terrestrial records. As additional records with high temporal resolution are generated from the region, our understanding of the sensitivity of forests and other plant communities to relatively short-term climate shifts will be improved. Calibration of assemblage changes from terrestrial, estuarine, marine, and ice core records will expand our ability to model past climate events using coupled atmospheric and oceanic circulation models.

These long-term records also provide a context to evaluate more recent changes in plant communities due to land use changes since European colonization of southeastern North America. Land clearance has been shown to increase sedimentation rates in tributaries, estuaries, and bottomland forests (Brush, 1984; Willard et al., 2003, 2011), and secondary and tertiary forests now mantle much of the southeastern United States. Restoration efforts for degraded ecosystems such as the Florida Everglades and Chesapeake Bay are relying upon floral and faunal-based reconstructions of the natural variability of the ecosystem to develop sustainable restoration goals in the context of modern conditions and predicted future warming. The increasing use of multiple proxies (i.e., pollen, plant macrofossils, organic biomarkers) provides a promising means to improve reconstructions of different climatic and

environmental parameters. Further improvements in dating techniques and our understanding of radiocarbon reservoir corrections in different depositional settings should allow interpretation of vegetation changes over decadal- to centennial timescales. Such records are critical to understand the magnitude and rates of vegetation change under natural climate variability. The resulting understanding of vegetation and terrestrial response to different modes of climate variability provides a context to evaluate anthropogenic impacts on southeastern United States forests and their likely response to a range of future climate and land use scenarios.

Landscape and Climate

Dynamic change and great vertical and spatial diversity have characterized the Holocene vegetation of the western and southwestern portions of the North American continent. In the United States, this region encompasses the modern states of California, Nevada, Utah, Arizona, New Mexico, and adjacent regions of Oregon, Idaho, and Texas and, in northern Mexico, the states of Baja California, Baja California Sur, Sonora, Sinaloa, Chihuahua, Durango, and western Coahuila. Driven by the interaction of climate, topography, and distance from the Pacific Ocean for some areas and from the Gulf of Mexico in other areas, vegetation communities as diverse as desert shrub, semiarid woodlands, montane forests, and tundra can be found within relatively short distances of each other in the region. Topographically, the region varies from sea level coastal plains, deep interior depressions over 200 ft below sea level, to extensive interior plateaus sometimes lying above 1300 m with flanking mountain ranges with peaks well above 3000 m (Hunt, 1967). The north-south to northwest-southeast trending mountain ranges which dominate the region serve both to impede the flow of moisture-laden storms from the Pacific to the west and to channel monsoonal storms northward from the Gulf of California and the Gulf of Mexico.

For discussion purposes, the area can be divided into three large regions based upon the dominant climate. These include (1) most of California west of the crest of the Sierra Nevada Mountains and north of the Transverse Ranges at the southern end of the Central Valley, (2) the high-elevation interior plateau known as the Great Basin which lies east of the crest of the Sierra Nevada Mountains, and stretches to the Wasatch Range to the east and to the Ochoco Mountains in the north, and (3) the Desert Southwest which lies south and southeast of the Great Basin and south of the Transverse Ranges in southern California and extending into northern Mexico in both areas.

Coastal vegetation ranges from rainforest in the north to chaparral in the south. Before Euro-American settlement, the interior Central Valley was characterized by mixtures of shrubs, grasses, and other herbaceous plants in the north and graded southward into shrubby steppe. Oak-dominated deciduous woodlands flanked (and to a lesser degree still flank) the Central Valley on all sides. Lying above the deciduous forests, the intermediate-elevation slopes of the Sierra Nevada Mountains still support pine-dominated montane forests. These forests transition into pine-dominated subalpine woodlands at higher elevations and, at even higher elevations, to subalpine grasslands and tundra.

East of the crest of the Sierra Nevada Mountains, the lowest elevation basins in the Great Basin are characterized by shadscale (saltbush)-dominated desert shrub communities (Billings, 1951). On the surrounding slopes, these transition into sagebrush-dominated steppe. Piñon pine and juniper dominate semiarid woodlands that cover the intermediate mountain slopes of the region. In the case of the lower

mountain ranges in this region, semiarid woodland comprises the highest-elevation vegetation community. Limber pine-dominated subalpine woodlands are found above the semiarid woodland in a few of the higher ranges. Only the highest mountain ranges of the region support narrow zones of ponderosa pine- and white fir-dominated montane forests between the semiarid and subalpine woodlands. Subalpine grasslands and/or alpine tundra occur rarely above the subalpine woodland and only on the highest mountain ranges.

Similar to the Great Basin, the Desert Southwest is a region of dramatic contrasts in topographically governed microclimate and vegetation. Mojave Desert vegetation characterizes most of southern Nevada, eastern California, and northwestern Arizona. The most common valley floor vegetation community within the Mojave Desert is desert shrub dominated by creosote bush and white bursage. Joshua tree is characteristic of many of the alluvial fans surrounding the broad basins of this area. However, the vegetation of the region also includes a great diversity of other shrubs and cacti. In fact, desert vegetation diversity increases southeastward from the Great Basin into southern Arizona. In central Arizona, the Mojave Desert vegetation gives way to the richly diverse Sonoran Desert. A great variety of cacti characterize the vegetation communities of the Sonoran Desert. Saguaro cactus, paloverde, and brittlebush are common in these communities. In extreme southeastern Arizona and southwestern New Mexico, the Sonoran Desert gives way to the Chihuahuan Desert. Primarily a shrub desert lying above 1100 m, most of the Chihuahuan Desert lies further south in the Mexican states of Chihuahua, Coahuila, and parts of Durango, Zacatecas, Nuevo Leon, and San Luis Potosi (Lowe, 1977). Much of the altiplano is dominated by Chihuahuan Desert shrub vegetation. Tarbush, creosote bush, and whitethorn are among the most abundant species represented in these communities, though grasses, yuccas, and cacti are also common (Lowe, 1977). Changes in soils often result in dramatic shifts in vegetation community composition over very short distances in the Chihuahuan Desert (Lowe, 1977, p. 21).

Piñon pine and juniper codominate semiarid woodlands that cover many of the lower-elevation mountain ranges and the intermediate-elevation slopes of the higher ranges of the northern portion of the Desert Southwest (Lowe, 1977). Above this on the higher ranges in the western portion of this region, limber pine and, occasionally, white fir occur. With increasing elevation in the northeastern part of this region, semiarid woodland transitions into montane woodland dominated by ponderosa pine. Above this, fir becomes more common; on the highest mountains, spruce may be found mixed with fir.

In southern Arizona, however, oak and oak pine woodlands and chaparral replace piñon-juniper semiarid woodlands on intermediate-elevation slopes. Higher mountain ranges still support ponderosa pine at lower elevations in the montane forest and fir or spruce-fir forests at highest elevations. Climatologically, the three regions can be characterized by the seasonal distribution of rainfall and temperature. California north of

the Transverse Ranges can be divided into a northern area that is characterized by cool wet winters and warm dry summers. The southern portion of this area is dominated by warm moist winters and hot, dry to moist summers. In the Great Basin, cold, moist winters and hot, dry summers are the norm. The Desert Southwest is characterized by warm, dry winters and hot, moist summers. The climate of these regions reflects the effects of both the heterogeneous topography and the varying impact of three major air mass systems that intersect over it (Houghton et al., 1975). The predominance of these air masses varies both seasonally and annually to influence the weather of the region today. In the past, changes in their average position have resulted in significant changes in the distribution of vegetation communities within the region and upon the animals and peoples that have depended upon them. These systems converge upon the central Great Basin from the west, southeast, and northeast and can be described as follows:

- *Pacific*: a regime dominated by maritime polar air masses. These moist, cool air masses sweeping in from the Pacific Ocean to the west produce cool, wet winters, and their absence in summer makes the growing season hot and dry.
- *Gulf*: a regime dominated by maritime and continental tropical air masses. These warm, moist air masses entering the southwest from either the Gulf of Mexico or the Gulf of California to the south produce hot, moist summers with midsummer torrential rainfall (originating during convective storms) and warm dry winters.
- *Polar*: a regime dominated by continental polar and Arctic air masses. These cold dry continental air masses drop down from the North American interior and extend into the Great Basin from the northeast during the winter.

Movements of these air systems, and their impact on local and regional climate, are reflected in changes in hydrology, erosion and deposition processes, and vegetation. Displacement of winter and summer storm tracks and variations in the penetration of the summer monsoon are all affected by the realignment of these pressure systems through time.

Pollen Records

Climate not only affects the spatial distribution of vegetation in the region, but it also determines where well-preserved pollen records are found. The distribution of pollen (palynological) evidence in the region is primarily constrained by moisture differences. The major sources of late Quaternary pollen records in the greater southwest include lacustrine and marsh deposits, dry cave sediments, alluvium and cienega deposits, and ancient woodrat middens (a source unique for the North American record).

In general, the number of well-preserved pollen records from aquatic environments at all elevations decreases southward in this region, reflecting the greater rarity of lakes and marshes due to greater aridity. Most lacustrine records span only a few thousand years, though some span the full Holocene and, in rare cases, extend well into the Pleistocene. Springs and associated ephemeral ponds are the primary source for well-preserved Holocene pollen records in the southern portion of

this region. These often provide records spanning the Holocene; however, the destruction by drought of pollen during the middle Holocene drought is often a problem. Also, they are often complex and difficult to interpret because of dramatic changes in deposition rates and occasional hiatuses. However, high organic production at some of these sites resulting in rapid rates of sediment accumulation makes them amenable to the formation of high-frequency vegetation histories. Such records can be compared with tree-ring data to generate detailed records of regional climate dynamics and vegetation response.

Pollen from ancient woodrat middens usually is excellently preserved by the urine that encases the nest materials. Thus, they can provide very detailed records of past vegetation. However, their interpretation must be constrained by the fact that they primarily represent the collecting activities of woodrats. These activities actually provide some pollen types which may be underrepresented or absent from the airfall pollen record. Because they are usually found in sheltered localities, woodrat middens have much less airfall pollen than open locations. Woodrat midden pollen samples are obtained from the radiocarbon-dated layers of crystallized urine-encased nest materials that comprise an ancient nest (Betancourt et al., 1990). Each pollen spectrum obtained from individual layers represents a single 'snapshot' of a particular point in time at a specific place on the landscape.

Alluvial, cienega, and cave pollen samples from the North American west and southwest suffer from stratigraphic or, more specifically, chronometric problems. Alluvial and cienega deposits can represent highly variable depositional environments that contain scant organic materials for radiocarbon dating. Deposits in the dry caves of the interior often contain abundant well-preserved pollen, as well as material for radiocarbon dating, but because rodents nest in the loose deposits, they are often heavily mixed. In comparison with mechanically abraded alluvial pollen, and cienega pollen that has been subject to episodes of degradation, cave deposits are often extremely well preserved.

The Data

Pollen records from the west and southwest are not as abundant as those from the eastern or northwestern portions of North America. In addition, many of the analyzed records have either not been published or are only partially published. Many are only recorded in doctoral dissertations, master's thesis, or project reports or 'gray literature.' More recently, some have been published on the Internet. The coverage in this article is primarily restricted to those sites that have recently been published in peer-reviewed literature and provide more detailed, regionally representative vegetation and climate histories. In a few cases, however, some 'gray literature' will be included where it provides needed continuity in the chronometric and spatial pollen record. Older palynological research is summarized in several review articles by Mehringer (1985), Hall (1985), Adam (1985), Mehringer (1986), and Martin and Mehringer (1965), and more recent research in the Great Basin by Wigand and Rhode (2002).

The Holocene vegetation record from the west and southwest is as diverse as its landscape. However, it can be

characterized by several general trends as well as by crosscutting climatic events that are encountered in most of the region. These events can be tracked by tracing the response of climate indicator plant species that are characterized by wide spatial distributions and relatively rapid response to changes in climate. Differences in the magnitude of these events from one area to the next reflect the varying predominance of the major climate influencing air masses discussed above. Some of the salient trends and crosscutting events from a regionwide perspective are summarized below. Select sites will be briefly discussed later. Note that dates have been given in calibrated years before present (cal BP) and radiocarbon years BP (rcyr BP).

Vegetation and Climate History of the North American West and Southwest

General Summary

The Pleistocene/Holocene transition has been variously placed at about 13 900 cal BP (12 000 rcyr BP) or 11 540 cal BP (10 000 rcyr BP) based upon geologic, glacial, botanical, or other criteria. We will simply indicate that the major break in vegetation assemblages between the Pleistocene and Holocene in the west is based upon the use of dendrograms generated by dissimilarity coefficient analysis of pollen spectra. These analyses place the break between the Pleistocene and the Holocene usually about 13 900 cal BP (12 000 rcyr BP) to 13 470 cal BP (11 500 rcyr BP). The interval following this break, which corresponds to the Younger Dryas in Europe, is usually characterized by initial drought followed by effectively moister conditions between 13 120 cal BP (11 200 rcyr BP) and 11 920 cal BP (10 200 rcyr BP), probably driven by colder temperatures and reduced evaporation rates rather than by an increase in precipitation. The vegetation of that interval is purely Holocene in nature.

Warm, moist conditions seem to have predominated much of the interior of the region between 11 920 cal BP (10 200 rcyr BP) and 9530 cal BP (8500 rcyr BP). These conditions may have resulted from increased late spring through mid-summer precipitation as shown by the pollen record, woodrat midden plant macrofossils (Wigand and Rhode, 2002), and spring discharge in the northern Mohave Desert (Quade et al., 1998).

During the middle Holocene, much warmer and drier conditions seem to have prevailed in much of the northern portion of the interior west between 8910 cal BP (8000 rcyr BP) and 6290 cal BP (5500 rcyr BP). However, between 9660 cal BP (8600 rcyr BP) and 6290 cal BP (5500 rcyr BP) the southern part of the region apparently enjoyed a significant increase in late spring or mid-summer rainfall. These monsoonal climates gave way to conditions that were relatively drier after 3030 cal BP (2800 rcyr BP). Between 6440 cal BP (5600 rcyr BP) and 6290 cal BP (5500 rcyr BP) a major episode of increased winter precipitation recorded from pollen localities as far north as the Plateau of eastern Washington to well into the northern Mojave Desert, and southern California brought the middle Holocene drought to a sudden halt. Although there was a brief return to slightly drier conditions after this event, climate was never as severe as before 6290 cal BP (5500 rcyr BP).

Increasing winter precipitation after 5820 cal BP (5000 rcyr BP) climaxed in the northern interior between 4570 cal BP (4000 rcyr BP) and 2670 cal BP (2600 rcyr BP) during the

Neopluvial. Renewed drought cycles characterized the interval between 2670 cal BP (2600 rcyr BP) and 1700 cal BP (1700 rcyr BP), but were interrupted by a dramatic winter wet event centered between about 2140 cal BP (2100 rcyr BP) and 1850 cal BP (1900 rcyr BP). Between about 1700 cal BP (1700 rcyr BP) and 910 cal BP (1000 rcyr BP) increased grass abundance, piñon pine expansion, and increased water depth in previously marginal ponds during the summer confirm a period of highly variable, near-decadal variations in precipitation with a shift from winter to late spring to mid-summer dominance.

A return to winter-dominated precipitation in the northern portion of the region about 910 cal BP (1000 rcyr BP) signaled the beginning of generally much drier conditions, punctuated by a significant warm, moist event about 690 cal BP (730 rcyr BP). A return to drier conditions followed until about 240 cal BP (250 rcyr BP), when a return to cooler, moister conditions may signal the last phase of the Little Ice Age in the region. These conditions ended about 150 years ago. Vegetation since then probably reflects the impact of both the Euro-American settlement as well as climate. A few key pollen records whose locations can be found on [Figure 1](#) are discussed below.

The Details

Coastal California The Clear Lake microfossil record from the north central coastal range of California reveals the dramatic shift from pine and cypress (*Pinus* and *Cupressaceae*) family dominated conifer forest to oak (*Quercus*)-dominated

Figure 1 Location of published, radiocarbon-dated Holocene pollen records from the western and southwestern United States mentioned in the text. Most of these are not in the NOAA National Climatic Data Center's North American Pollen Database. The sites are 1, Diamond Pond; 2, Fish Lake; 3, Wildhorse Lake; 4, Clear Lake; 5, Little Valley; 6, Lead Lake; 7, Hidden Cave; 8, Ruby Marshes; 9, Crescent Spring; 10, Exchequer Meadow; 11, Lower Pahranaagat Lake; 12, Tulare Lake; 13, Ballona Estuary; 14, San Joaquin Marsh; 15, Montezuma Well; 16, Twin Lakes; 17, Beef Pasture; 18, Double Adobe; and 19, Summit Lake.

deciduous forest during the Pleistocene/Holocene transition (Adam, 1988; see (Northwestern North America)). With a sample roughly every 500 years, this record reveals a maximum extent of oak forest about 8340 cal BP (7500 rcyr BP). Thereafter, various shrubs and low-growing trees in the buckthorn family (*Ceanothus* and *Rhamnus*) became more abundant, remaining so (except for the period between about 4570 cal BP (4000 rcyr BP) to 2670 cal BP (2600 rcyr BP)) until the present (Adam, 1988). Chinquapin (*Chrysolepis*), alder (*Alnus*), willow (*Salix*), and less commonly sagebrush (*Artemisia*) and grasses comprise the major part of the Holocene plant community in the area.

In east central California the record from Exchequer Meadow located in the montane forest on the west slope of the Sierra Nevada Mountains indicates that the transition from a sagebrush-dominated alpine tundra and wet sedge meadow community to a pine (*Pinus*)-fir (*Abies*)-dominated montane forest had begun as early as 13 910 cal BP (12 000 rcyr BP) (Davis and Moratto, 1988). However, it was not fully established until about 9530 cal BP (8500 rcyr BP). Lower elevation deciduous oak forest expansion is reflected in the rise of oak (*Quercus*) pollen about 13 470 cal BP (11 500 rcyr BP), but it is not until about 10 130 cal BP (9000 rcyr BP) that it is clearly

well established at lower elevations in the region. After a middle Holocene lull, renewed abundance of sedge (Cyperaceae) pollen about 6290 cal BP (5500 rcyr BP) reflects increased regional moisture evidenced in pollen records elsewhere in the region (Davis et al., 1985).

The Holocene portion of a pollen record from the Tulare Lake Basin near the southern end of the Central Valley records a history of lake and marsh fluctuation in its littoral vegetation, primarily sedge and cattail (*Typha*) pollen, and pelagic algae (primarily *Pediastrum* sp. and *Botryococcus* sp.) (Davis, 1999) (Figure 2). The absence of a pollen or algae record for the interval about 11 500 BP may indicate that the basin was totally dry during the so-called Clovis drought (Davis, 1999, Figure 3; Haynes, 1991). Pollen from the base of the Holocene section of the Tulare Lake core dating to about 11 540 cal BP (10 000 rcyr BP) suggests that by about 11 920 cal BP (10 200 rcyr BP), marsh vegetation (as indicated by the presence of littoral vegetation pollen) is restricted, but the abundance of pelagic algae at about 10 020 cal BP (8900 rcyr BP) and 8860 cal BP (7900 rcyr BP) indicates at least two episodes of deep lake (Davis, 1999, Figure 3). The terrestrial pollen indicates the nearby presence of an extensive juniper woodland with a

Figure 2 Comparison of reconstructed Holocene high lake stands of Tulare Lake with ratios of littoral marsh species and pelagic algae. High stands were mapped in shoreline trenches by Dr. R. Negrini and this author between 2003 and 2007. The ratio of *Pediastrum* to *Botryococcus* algae indicates slightly more oligotrophic (fresher) water conditions versus more eutrophic (stagnant) water conditions. *Pediastrum* abundance suggests recent recharge of the lake. The sedge-to-cattail ratio reflects marsh extent and stability. Cattails appear when there is renewed influx of fresher water into the Tulare Lake Basin. Sedges predominate when there are extended periods of low water. Note that sedge is usually abundant between high lake stands and lower during high lake stands. The algae and pollen used in these ratios have been standardized with respect to pollen abundance per sample so that they reflect actual increases and decreases in the pollen of these species in the record.

sagebrush understory that disappeared by 8910 cal BP (8000 rcyr BP) to be replaced by a saltbush (*Chenopodiaceae-Amaranthus* pollen)-dominated desert shrub community. Copious sunflower family (primarily *Aster*-type) pollen from the Holocene record suggests the abundance of both shrubs and forbs of the Asteraceae around Tulare Lake (Davis, 1999, Figure 3). The greatest abundance of aster-type pollen occurs between 7880 cal BP (7000 rcyr BP) and 6290 cal BP (5500 rcyr BP), suggesting increased late-spring to middle-summer precipitation. Oak pollen from the Tulare Lake record suggests that oak was regionally common in the hills surrounding the basin between 10 130 cal BP (9000 rcyr BP) and 3830 cal BP (3500 rcyr BP) (Davis, 1999, Figure 3).

After episodic middle Holocene drought, increasingly wetter conditions are marked by the expansion of littoral vegetation about 5220 cal BP (4500 rcyr BP) (Davis, 1999, Figure 3). The Holocene climax of marsh expansion about 4660 cal BP (4100 rcyr BP) is followed by an abrupt decline of littoral vegetation and its replacement by pelagic algae,

indicating that water depth in the Tulare Lake Basin rose rapidly to drown the marsh, resulting in a dramatic expansion of the lake just after 4570 cal BP (4000 rcyr BP) (Davis, 1999, Figure 3). The climax of pine pollen (a reflection of increased winter rainfall) in the Tulare Lake record at the same time as the pelagic algae (about 2880 cal BP (2700 rcyr BP) to 3030 cal BP (2800 rcyr BP)) suggests a regional increase in precipitation at that time (Davis, 1999, Figure 3). Extremely low charcoal abundance during this interval also suggests wetter conditions. Increasing saltbush pollen coupled with decreasing pine, oak, and littoral vegetation pollen, as well as declining pelagic algae abundance, suggests significantly drier conditions during the last 1980 cal BP (2000 rcyr BP) (Davis, 1999, Figure 3).

A 7-ka-long pollen record from the San Joaquin Marsh provides additional evidence that coastal southern California had a moister climate during the middle Holocene (Davis, 1992). Prior to 3200 cal BP (3000 rcyr BP), pollen from *Aster*-type plants dominated the pollen record (Davis, 1992, Figure 3). After that, pollen from plants from the saltbush family

Figure 3 Comparison of the ratio of *Ceanothus* + *Labiatae* + *Rosaceae* to *Artemisia* pollen for both Playa Vista Cores 1 and 8. The primary source of *Ceanothus*, *Labiatae*, and *Rosaceae* pollen is the moister climate coastal chaparral. *Artemisia* (primarily California sagebrush) is characteristic of the drier coastal chaparral. The period of greatest chaparral expansion between 8000 and 5000 rcyr BP corresponds to events throughout the southwestern United States.

predominates. In addition, the greater abundance of pine, oak, buckthorn (*Ceanothus*), and sagebrush pollen provides further evidence of moister climate. Higher values of Liguliflorae-type pollen prior to 5820 cal BP (5000 rcyr BP) suggest that this moisture may have been in the form of late-spring through midsummer precipitation. Ongoing reanalysis by this author of pollen from 12- to 16-ka-long cores from the Ballona Estuary in the southwest corner of the Los Angeles basin confirms this conclusion. There, pollen from shrubs in the mint (*Lamiaceae*), buckthorn (*Ceanothus*), and rose (*Rosaceae*) families increases in abundance, indicating a major chaparral expansion between 8 and 5 ka ([Figure 3](#)).

A pollen record from Laguna Canyon south of Los Angeles indicates that lake level rose as a result of increased winter precipitation along the southern coast of California, resulting in extensive flooding of the surrounding valley floor. Sustained flooding established a sedge-rich marsh, though there was some tall coastal cattail as well. For brief intervals, the lake levels may have been slightly deeper, allowing the establishment of emergent aquatic plants such as water smartweed. The lake(s) may have ended not as a result of drier climate but probably as a result of a breach in the sill which maintained the lake in Laguna Canyon.

Summer paleoclimatic reconstructions using tree-ring records have been utilized in analyzing the salt variations in Soda Lake, a saline lake in the Carrizo Plain just east of the Temblor Range in the southeastern portion of the Central Valley of California. Limber pine tree-ring cores from the Transverse Ranges just south-southeast of Soda Lake indicate that there is a relatively strong correspondence between mesic and xeric conditions and the percentage of salt in the lake and possibly in the kind of salt being precipitated. The analysis also documented a major expansion of Jeffrey pines onto the upper mountain slopes, beginning about 225 years ago. Stand establishment dates indicate that limber pines dominated the upper mountain slopes during the last millennium until 225 years ago, when Jeffrey pine became dominant. This shift indicates both a lengthening of the growing season in the area and a post-Little Ice Age increase in precipitation. This research is ongoing but holds tremendous promise for tracking the climate of the last few hundred years in the region.

Great Basin. Three pollen records from an elevational transect up the west slope of Steens Mountain in south central Oregon provide a record of Holocene vegetation change ([Mehring, 1985, 1986](#); [Wigand, 1987](#); [Johnson et al., 1994](#)). The longest record from Fish Lake (2250-m elevation) provides a 13-ka record of high-elevation sagebrush community dynamics. A ratio of sagebrush to grass pollen indicates that drier conditions predominated between 8910 cal BP (8000 rcyr BP) and 6290 cal BP (5500 rcyr BP) ([Mehring, 1985](#)). During the same interval, sagebrush became more common than grass around Wildhorse Lake at 2565-m elevation. The 9.4-ka-long record from Wildhorse Lake indicates that grasses did not regain their early Holocene dominance until after 4570 cal BP (4000 rcyr BP) ([Mehring, 1985](#)). Diamond Pond, at 1265 m at the base of the northwest slope of Steens Mountain, records the shifting boundary between the lower sagebrush and desert shrub communities during the last 6000 radiocarbon years. A brief but major wet episode about 6290 cal BP (5500 rcyr BP) resulted in a shift from greasewood

(*Sarcobatus*) to sagebrush predominance in the shrub communities around Diamond Pond. Between 4570 cal BP (4000 rcyr BP) and 1980 cal BP (2000 rcyr BP) a further shift to wetter conditions resulted in the expansion of western juniper (*Juniperus occidentalis*) in the volcanic complex around and east of Diamond Pond ([Mehring and Wigand, 1990](#)). Close correspondence between the pollen record from Diamond Pond and the macrofossil record from ancient woodrat middens in the same area documents the actual arrival and subsequent departure of western juniper. Juniper macrofossils from the ancient woodrat middens also permitted direct identification of western juniper in the pollen record from Diamond Pond ([Mehring and Wigand, 1990](#)).

The charcoal record reconstructed from microscopic charcoal counted on the pollen slides reveals a dynamic relationship between fuel accumulation during wet climate episodes and fire during subsequent drought in the Diamond Craters complex ([Wigand, 1987](#)). It also indicates that when climates became sufficiently dry after 1980 cal BP (2000 rcyr BP), catastrophic fires resulted in the ultimate demise of juniper woodland at lower elevation sites, such as those around Diamond Craters ([Figure 4\(a\)-4\(c\)](#)). Such fires characterized other intervals as well, when forests that expanded during episodes of wetter climate were destroyed at their lower elevational distribution by fire. Increased grass pollen relative to juniper pollen between 1630 cal BP (1600 rcyr BP) and 910 cal BP (1000 rcyr BP) indicates a period when the precipitation

Figure 4 (a) Influx rates of two sizes of charcoal at Diamond Pond, Oregon, for the ~6000 years. Charcoal abundance (as a measure of fire frequency and magnitude) shifts on a centennial to millennial scale. (b) In general, charcoal increases in abundance and size during extended episodes of wetter climate. On the other hand, it decreases in abundance and size during extended episodes of drier climate. During the transition from a period of drier climate to one of wetter climate, charcoal abundance (fire occurrence) is lower than during the later part of a mesic episode when periodic droughts begin to punctuate the wet episode. (c) Comparison of the charcoal-to-pollen ratio from Diamond Pond and Summit Lake in the northern Great Basin. Diamond Pond is located on the ecotone between the desert shrub and lower sagebrush communities. Summit Lake lies within the upper sagebrush community in the Black Rock Range of north central Nevada. There are other charcoal records in the region that are similar in the timing of charcoal abundance suggesting periods of increased fire frequency due to climate.

Figure 4 (Continued)

pattern shifted from winter-dominated to a late-spring through midsummer pattern (Wigand, 1987).

A regionally restricted and very brief climate event is found in a transect of pollen records stretching from Sardine Meadow (south of the Sierra Valley) on the western end, through Summit Lake in the Black Rock Range, to Grays Lake in southeastern Idaho. These records have revealed a striking warm, wet event ~730 rcyr BP that does not appear in records north or south of this swath (Figure 5). Today, this stretch of the northern Great Basin is unique in having high May and June precipitation relative to winter precipitation. Each of the pollen records mentioned above shows a dramatic increase in aquatic plant and algae production. In the Sierra Valley northwest of Reno, NV, this coincides with an archaeological site comprised of over 49 hearths that may have been used to process camas root (Wigand, 2003; Wigand, 2004a,b).

In the western Great Basin south of Reno, Nevada, a 5.5-ka-long record from Little Valley provides additional evidence of a period of wetter climate between 4580 cal BP (4000 rcyr BP) and 1980 cal BP (2000 rcyr BP) ago (Wigand and Rhode, 2002). Lying in the montane forest just east of Lake Tahoe,

the pollen from the Little Valley core reveals increasing pine abundance relative to sagebrush after 6290 cal BP (5500 rcyr BP). Increased alder, birch (*Betula*), and willow pollen between 4580 cal BP (4000 rcyr BP) and 1980 cal BP (2000 rcyr BP) indicates cooler, wetter conditions in the Little Valley meadows (Wigand and Rhode, 2002, Figure 11).

Expansion of marshes in the Carson Sink west of the Stillwater Mountains, as a result of increased precipitation and runoff from the Sierra Nevada Mountains during this interval, is confirmed by the appearance of abundant cattail pollen in the deposits of Hidden Cave (Wigand and Mehringer, 1985, Figure 36). Cattail pollen may have arrived naturally but most probably reflects human activity in the cave. However, today, the nearest marsh is kilometers distant from the cave, and its presence in the cave between 4 and 3 ka suggests that marshes were probably much closer to the site. Wetter conditions between 4580 cal BP (4000 rcyr BP) and 3200 cal BP (3000 rcyr BP) are confirmed by the relative increase in sagebrush pollen relative to saltbush (*Chenopodiaceae*) pollen at Crescent Spring, Utah, in the northwestern Bonneville Basin (Mehringer, 1985, Figure 11). Late Holocene precipitation

Figure 5 Pollen records in a band across the northern portion of the Great Basin are not revealing an episode of warm, moist climate centered about 730 rcyr BP. Key pollen and acid resistant algae types in records stretching from the Modoc Plateau to Gray's Lake in southeastern Idaho reveal a sudden increase in the discharge of springs and an increase in marsh depth. They also indicate a dramatic increase in the productivity of aquatic plant pollen and algae reflecting fresher water conditions and warmer climate. Here, the key pollen and algae in a record from northern California and north central Nevada are compared.

increase stands in stark contrast to the severe middle Holocene drought recorded in pollen from the sediments of Hidden Cave (Wigand and Mehringer, 1985) and from lake and marsh sediments in the Ruby Valley of east central Nevada by Thompson (1992).

Additional analysis of the Hidden Cave pollen record and of grain-size analyses run on many of the same strata from which the pollen was taken reveal a very close relationship between vegetation dynamics and surficial processes in the Carson Sink (Figure 6). During intervals of dramatic climatic transition ~8910 (8000) and 4580 (4000) years ago (when climates were transitioning into and out of the middle Holocene drought), vegetation assemblages fluctuate wildly. During the same interval, sediment analysis indicates that numerous colluvial sediment units are deposited in Hidden Cave. On the other hand, when vegetation was transitioning from late Pleistocene juniper woodlands and marshes bordering the Carson Sink about 10 130 cal BP (9000 rcyr BP), sediment analysis indicates an increase in units rich in aeolian sediments. This indicates that as the lake and marshes were drying, aeolian erosion and deposition began to increase (Wigand, 1997).

We have also found that comparison of ratios of several of the dominant pollen types found in the Hidden Cave record differentiates periods of summer/spring precipitation from periods of winter-dominated precipitation. The ratio of

'saltbush/sagebrush' pollen reveals the sequence of dry and wet cycles for the last 11540 cal BP (10 000 rcyr BP) (Figure 7). On the other hand, the ratio of 'grass/greasewood' pollen reveals the pattern of intervals when spring and summer precipitation becomes more common versus a winter-dominated precipitation pattern. This is also indicated by a rise in single-leaf piñon (*Pinus monophylla*) pollen.

A 2.3-ka-long core from the Carson Sink east of Fallon, Nevada, provides additional evidence of the late-spring through midsummer shift in annual precipitation, documented in the Diamond Pond core. A significant increase in pine pollen relative to juniper pollen between 1630 cal BP (1600 rcyr BP) and 910 cal BP (1000 rcyr BP) corresponds to an expansion of single-leaf piñon documented in the ancient woodrat nests of the region (Wigand and Rhode, 2002, Figures 13 and 14).

A recent pollen record from Pyramid Lake (Mensing et al., 2004) suggests that the early middle Holocene (7520 cal BP (6600 rcyr BP) to 6290 cal BP (5500 rcyr BP)) was extremely dry, although it included one short but intense wet phase. Evidence of a greatly reduced volume and depth of Pyramid Lake suggests that Lake Tahoe probably did not overflow its rim during this interval. The climate became much more mesic after 6180 cal BP (5400 rcyr BP) with episodes of moister climate corresponding with the Neopluvial between 4580 cal

Figure 6 Ratios of major pollen types in samples from Hidden Cave compared with grain-size analysis of sediments of the same samples indicate a strong correlation between climate, vegetation response to climate change, and the dynamics of dominant surface erosion processes. Colluvial processes are responsible for most of the postglacial sediments that occur in the cave, but their nature varies considerably through the Holocene. Occasionally, the sediments are characterized by coarse grain size and poor sorting. This indicates that there was significant, high-energy slope wash, probably due to high precipitation events. At other times, the sediments are characterized by finer particle size and contain abundant aeolian sands that were deflated from the drying lake bottoms and marshes that lie near the cave. These sediments were deposited on the slopes above the cave and then swept into the cave during heavy rainfall events. At Hidden Cave, the early Holocene shift toward drier conditions (as the vegetation cover became less dense and pluvial Lake Lahontan dried) was punctuated by highly variable erosion rates dominated by high-energy colluvial events reflecting torrential rains. During the middle Holocene, aeolian sediments become more abundant and form a large portion of the cave's sediments though they are still being brought into the cave as colluvium. During the transition between the middle and late Holocene, colluvial sediments in the cave become coarser again and highly variable in their nature reflecting greater variability in climate as well as an increase in precipitation. Vegetation lagging behind the increase in precipitation cannot serve as a competent armor against soil erosion until its biomass has increased significantly.

Figure 7 Ratios generated from some of the climate indicator pollen species in the pollen record at Hidden Cave offer a potential opportunity to monitor shifts in the seasonality of precipitation for the entire Holocene. In particular, the shift in predominance of winter versus summer precipitation is extremely important when the dynamics of vegetation around the cave and erosion processes are studied. The ratios of saltbush to sagebrush and grass to greasewood are used to reflect seasonality. An increase in both sagebrush and grass reflects increased winter precipitation. An increase in the abundance of both grass and greasewood without an increase in sagebrush pollen abundance indicates summer-shifted precipitation. That is, grass abundance increases in response to increases in both summer or winter precipitation. Sagebrush only increases with increased winter precipitation. However, when both saltbush and grass abundance increase (without an increase in sagebrush), a shift to summer-dominated precipitation is indicated. This diagram reveals several significant shifts between periods dominated by summer rainfall and others dominated by winter precipitation. In general, neither winter nor summer precipitation characterizes the area around Hidden Cave. However, there are some episodes where the shift is pronounced and persists for some time.

BP (4000 rcyr BP) and 1980 cal BP (2000 rcyr BP) (Mensing et al., 2004, Figure 5). The past 2.4 ka appear to have had three cycles of wetter climate (Mensing et al., 2004, Figure 5). One was centered around 1630 cal BP (1600 rcyr BP) and corresponds to the period of late-spring to summer-shifted precipitation postulated elsewhere (Wigand and Rhode, 2002). Wetter climate between 1132 cal BP (1100 rcyr BP) and 780 cal BP (800 rcyr BP) corresponds with a return to increased winter precipitation in the northern Great Basin (Wigand, 1987) and between 390 cal BP (350 rcyr BP) and 170 cal BP (150 rcyr BP) with the 'Little Ice Age' (Wigand and Rhode, 2002). The timing and magnitude of the Pyramid Lake wet/dry cycles compares favorably with those found in other pollen records (Wigand, 1987; Wigand and Rhode, 2002), in stable isotope data (Benson et al., 2002), in ancient woodrat midden records (Tausch et al., 2004; Mehringer and Wigand, 1990), and with ages of submerged rooted stumps along the eastern Sierra Nevada (Stine, 1994; Lindstrom, 1990). These drought episodes appear to correspond with the timing of ice drift minima (solar maxima) identified from North Atlantic marine sediments (Mensing, 2004).

Mensing et al. (2008) review the pollen evidence from four sites revealing evidence of drought within the Great Basin during the last 2000 years. Using pollen ratios of climate indicator species indicating drier versus moister climate, they reveal periods of drought conditions. They then compared those records with the ages of tree stumps submerged beneath lakes in the western Great Basin, tree-ring chronologies, pack rat middens, and $\delta^{18}\text{O}$ data from sediments. Mensing and his

colleague's pollen records provide evidence of the magnitude of some of the droughts of the last two millennia. Their pollen records indicate that the climate between 2000 and 1800 cal BP was dry, with the driest sites being in the western Great Basin. The century ending ~1200 cal BP may have been dry, but the pollen record does not support severe drought. Their high-resolution pollen records from Pyramid Lake and Mission Cross Bog clearly identify a drought ending ~800 cal BP (350 rcyr BP) and 170 cal BP (150 rcyr BP) cal BP, whereas only the Pyramid Lake record indicates a drought ending at 550 cal BP. Evidence for more mesic climate at this time in northeastern Nevada suggests that this drought may have been fairly localized.

At the eastern edge of the central Great Basin, a record from Blue Lake, UT, analyzed by Louderback reveals a latest Pleistocene through Holocene record of vegetation change (Louderback and Rhode, 2009). Data from the upper 4 m of the core reveal that when Lake Bonneville occupied the Blue Lake site, pine and sagebrush communities characterized the nearby shorelines following a decline in lake level after ~12 000 cal BP. Wetlands developed by ~11 900 cal BP. Bulrush-dominated marshes were established no later than 10 800 cal BP. The Blue Lake wetlands desiccated during a warm, dry early middle Holocene ~8300–6500 cal BP. More mesic conditions beginning ~6500 cal BP are documented by the return of marshes at the expense of playa and grass (probably salt grass) meadow communities.

Regionally, sagebrush abundance increased relative to desert shrub species. Single-leaf piñon pine migrated into the

Figure 8 Comparison of drought indices generated from the pollen of climate indicator plant species at four western US pollen localities in the Intermountain West. They range from Carp Lake in the north to Lower Pahranaagat Lake in the south. Allowing for slight differences in the position of the climatic events due to the vagaries of radiocarbon dating, there is significant similarity between the records. Differences usually reflect the origin point of the event. If the source of moisture driving a wet episode or period is the northern Pacific, that event is strongest in the northern portion of the west and at higher elevations. If the event is derived from monsoonal rains, the event is stronger in the southern portion of the west. The plant species used in these ratios vary only in order to select the most representative wet versus dry climate indicator plant species from each site.

region (probably the nearby Goshute Mountains) after ~8000 cal BP. Late Holocene fluctuations include cooler and relatively moister intervals from ~4400 to 3400 and ~2700 to 1500 cal BP (these coincide with those in the Diamond Pond record). Warmer conditions between ~3400 and 2700 cal BP and after 1500 cal BP are also revealed in the pollen record from Blue Lake.

Desert West A high-resolution pollen record from Lower Pahranaagat Lake, about 90 km north-northeast of Las Vegas, Nevada, records about 4090 cal (3700 rcyr) of low-elevation vegetation dynamics in the northern Mojave Desert (Wigand and Rhode, 2002, Figure 17). With a sample about every 14 years for the span of the record, very high-frequency climate cycles could be identified and compared with long tree-ring

records in the region (Wigand and Rhode, 2002, Figure 17). Although the magnitude is not as great as in the northern Great Basin records, the three major wet phases of the Neopluvial between 4000 and 2000 rcyr BP are also evident (Figure 8; Wigand and Rhode, 2002, Figure 18). These were first recorded at Diamond Pond. In addition, the period of late-spring to midsummer-shifted precipitation recorded in northern and western Great Basin pollen records is also prominent in the pollen sequence from Lower Pahranaagat Lake (Wigand and Rhode, 2002, Figure 18).

Radiocarbon dates on peats and spring deposits at Ash Meadows, a huge spring complex with great time depth, have revealed at least three intervals of early to middle Holocene spring resurgence. These events took place about 9200 cal BP, about 8100 cal BP, and finally about 6800 cal BP. The earliest episode appears to be associated with the appearance of springs in areas where they do not currently exist, suggesting a much greater precipitation input than later during the Holocene. The other two episodes appear to be similar to other middle to late Holocene spring events.

Stable isotope data extracted from single-leaf piñon pine and Utah juniper remains from ancient woodrat middens sampled near the Yucca Mountain high-level nuclear waste storage facility study area reveal a pattern of variable physiological stress on these two species (Figure 9). As might be expected, piñon is less resistant to drought and temperature stress than is Utah juniper. When the stable isotope record is compared with the record of aeolian activity produced by Lancaster (1993), a clear relationship is demonstrated between physiological stress on both juniper and piñon resulting from climate variability. This is also reflected in the initiation and termination of periods of aeolian activity in southern Nevada (Figure 10).

Palynological investigations during the middle and late 1950s led Martin (1963) to propose a period of middle Holocene increased monsoonal precipitation for central and southern Arizona. He worked with pollen records obtained from cienega (marsh) deposits, where pollen preservation is often poor, deposition rates are highly variable, and some climatic episodes are missing from the stratigraphic record. Martin proposed that the climate of the middle Holocene of the Desert Southwest was characterized by heavy summer rains resulting in higher values of saltbush pollen. Martin associated increased values of *Aster*-type pollen with higher water tables, floodplain alluviation, fewer and lighter summer storms, and perhaps increased winter precipitation. If this is the case, then the record from Double Adobe IV suggests a Neopluvial moist episode similar to those seen between 4580 cal BP (4000 rcyr BP) and 1980 cal BP (2000 rcyr BP) in the northern Mojave Desert and the Great Basin (Martin, 1963, Figure 19). An extended period of increased *Aster*-type (Compositae) pollen is centered around 4250 cal BP (3800 rcyr BP) at Double Adobe. He also recorded that an early Holocene transition from *Aster*-type pollen dominance to saltbush-dominated pollen spectra occurred about 8860 cal BP (7900 rcyr BP) (Martin, 1963, Figure 20).

The Montezuma Well pollen sequence from central Arizona records over 10 ka of vegetation dynamics (Davis and Shafer, 1992). Declining values of pollen from the cypress family (probably *Juniperus*), ash (*Fraxinus*), and pine occurred between about 11540 cal BP (10 000 rcyr BP) and 8340 cal BP (7500 rcyr BP) (Davis and Shafer, 1992). Middle Holocene

Figure 9 Carbon isotope ($\delta^{13}\text{C}$) measurements were obtained on single-leaf piñon and Utah juniper macrofossils recovered from ancient woodrat middens spanning the Holocene in the northern Mojave Desert. The samples were obtained from middens within a hundred-kilometer radius of the Nevada Test Site. Each midden was represented by a paired (piñon and juniper) sample – in a few cases there is a juniper but no piñon sample. Elevationally, the middens were within a couple of hundred meters of each other. Carbon 13 is a measure of plant stress. As plants experience stress (either as a result of drought or frost during the growing season), the abundance of carbon 13 increases. The data plotted here indicate that (1) both piñon and juniper were more stressed by the middle to late Holocene shift to cooler annual temperatures than they had been by middle Holocene drier climates when summer precipitation characterized the area and (2) the piñon sample of each sample pair indicated greater stress in response to the change in climate than did juniper at the same locality.

Figure 10 The carbon 13 measurements plotted above are compared with dated aeolian dune activity in the northern Mojave Desert. In general, when carbon 13 values indicate higher stress on piñon and juniper, dune movement declines and ceases. On the other hand, dune movement characterizes intervals when plant stress decreases, but follows an episode of higher precipitation so that there is abundant alluvium available for aeolian transport.

drought, characterized by significantly increased values of saltbush pollen after 7880 cal BP (7000 rcyr BP) occurred at the same time that sedge pollen suffered a dramatic decline (Davis and Shafer, 1992). Saltbush pollen declined after 4570 cal BP (4000 rcyr BP), and cypress family pollen values increased,

suggesting an increase in regional precipitation contemporaneous with the Neopluvial event seen further north and west. Resurgence of sedge pollen values after 4570 cal BP (4000 rcyr BP) also substantiates the regional increase in precipitation (Davis and Shafer, 1992; see also Figure 8).

Two well-dated pollen records from extreme southwestern Colorado, Beef Pasture and Twin Lakes, reveal more detail of Holocene vegetation in the northeastern corner of the Desert Southwest. Beef Pasture lies near the base of the spruce zone in the La Plata Mountains, while Twin Lakes lies in the middle (Petersen, 1988). Spruce (*Picea*) pollen from the Twin Lakes record suggests that prior to about 8600 rcyr BP, spruce was not as abundant around the site. Two episodes between 9660 cal BP (8600 rcyr BP) to 6720 cal BP (5800 rcyr BP) imply that spruce reached its greatest Holocene density in the La Plata Mountains (Petersen, 1988, Figure 26; Petersen and Mehringer, 1976). This may have been driven by warm, moist, perhaps monsoonal climates in the early middle Holocene. Declining spruce pollen values from the Beef Pasture record indicate that climatic conditions became relatively drier after 3030 cal BP (2800 rcyr BP) (Petersen, 1988, Figure 27). This may reflect the same climatic transition that occurred near the end of the Neopluvial at Diamond Pond in the northern Great Basin and in other sites between the two areas.

Petersen (1988, 1994) attempted a reconstruction of the relative positions of the lower and upper spruce tree lines of the La Plata Mountains (Petersen, 1988, Figure 51). He believed that lower spruce treeline reflected the relative proportion of summer to winter precipitation. Upper treeline was influenced by temperature. He suggested that, except for a period between 1300 and 800 calendar years ago, upper treeline retreated to lower elevations for much of the last 2 ka (Petersen, 1988). Several episodes of lower spruce treeline retreat to higher slopes occurred during that same interval. The result was a dramatic shrinking of the spruce zone in the La Plata Mountains. Counts

of piñon-type pine pollen coinciding with the upslope retreat of spruce indicate a relatively increased summer to winter precipitation (Petersen, 1988, Figure 51). Petersen used this information to explain the success of Anasazi farmers in the Four Corners area during that interval.

In the desert regions of northern Mexico, the potential for reconstructing ancient vegetation and climate histories has been explored using the combination of plant macrofossils and pollen from ancient woodrat middens (Anderson and Van Devender, 1991). This technique fills a crucial proxy data void in a region that lacks pollen records from aquatic, dry cave, or alluvial contexts. Currently, only cursory vegetation histories and their possible paleoclimates have been reconstructed for the coastal lowlands of Sonora, Mexico (Anderson and Van Devender, 1995). In particular, the spatial movement of indicator plant species (e.g., piñon and creosote bush) has been reconstructed for very localized areas. However, as the spatial and temporal distribution of woodrat midden strata increases, the possibility of reconstructing more detailed vegetation and climate histories for the region will increase.

A final example of the value of utilizing ancient woodrat midden records to enhance the pollen records of the same region is the dated expansion of single-leaf piñon in the western Great Basin from the northern Mojave Desert. Directly dated piñon needles reveal the expansions and retreats of piñon during the last 22 000 years along the eastern front of the Sierra Nevada Mountains (Figure 11). This movement was controlled by changes in moisture and temperature during the late Quaternary.

Figure 11 The radiocarbon-dated movement of piñon pine along the eastern front of the Sierra Nevada Mountains. It seems to have begun its expansion from the extreme northwestern Mojave Desert and then used the Owens River and the foothills lying on either side as a corridor. When conditions improved (warmer and moister), piñon would expand. As conditions became cooler and/or drier, piñon would retreat.

Introduction

The South American continent is mostly covered by different tropical, subtropical, and temperate vegetation types forming a high number of very diverse ecosystems (Seibert, 1996). Important tropical rainforest ecosystems include the Amazon rainforests, especially in northern Brazil, the Atlantic rainforest, forming a small strip along the eastern Brazilian coast, and the Chocó rainforest, mostly distributed along the western Colombian Pacific coastal lowland.

The major tropical savanna ecosystems north of the equator are the Llanos Orientales in Colombia and the Orinoco Llanos in Venezuela. Other large savanna areas include the Gran Sabana in southeastern Venezuela, the Rupununi–Rio Branco savanna in Suriname, and the Roraima–Rupununi savanna in Brazil. South of the equator is the Cerrado, the major savanna region occurring mostly in central Brazil.

In northeastern Brazil, the semiarid Caatinga is the dominant vegetation type. In southeastern Brazil, there is a gradient from the coast to the inland, going from the Atlantic rainforest to the semideciduous forest, deciduous forest, and Cerrado. *Araucaria* forests and patches of grassland (Campos) cover the southern Brazilian highlands. Further south, in the southeastern South American lowlands Pampa, grasslands (Uruguay, Argentina), Chaco dry forests (Argentina), and the Patagonian steppe (Argentina, Chile) are the most important ecosystems.

The Andes are the major mountain system in South America, stretching along the western side of the continent from 5° N to 55° S. The variety of ecosystems in the Andes is very high, including altitudinal gradients from mountain rainforest, cloud forests, dry forests, deserts, high altitude Paramos, and Puna tundra grasslands, as well as latitudinal gradients from tropical, subtropical, and temperate vegetation types from rainforest to deserts. The Atacama desert is found on the coastal side of the central Andes and the Valdivian rainforest, and the *Araucaria* forests occur to the west of the southern Andes.

All those different vegetation types are related to different climatic conditions. In tropical South America, the annual precipitation and its temporal distribution are controlled by the seasonal migration of the intertropical convergence zone (ITCZ), which shifts from 7–9° N in January to 10–20° S in July, and by the topographic features of the continent. As a result, two different main climate types are represented in tropical South America: a climate without a dry season in the equatorial latitudes and climates with marked dry seasons north and south of the equatorial latitudes. North of the equator, the dry season lasts from October to March, and south of the equator, it occurs from April to September. For most of the savanna regions with seasonal climates, the annual precipitation ranges from 1200 to 2000 mm, and the average annual temperature is 20–26 °C. In northeastern Brazil, the ITCZ remains north of the equator and causes semiarid conditions with a long dry season of 6–11 months. The mean annual

rainfall is less than 250–750 mm. South America north of the equator is influenced by the northeasterly trade winds blowing from the Caribbean, whereas the region south of the equator is influenced by the Atlantic Southeasterlies, which originate from the subtropical high-pressure cell over the South Atlantic Ocean. The climate of the northern Andes is also influenced by the easterly trade winds. Advections of Antarctic cold fronts produce heavy rainfall when they meet tropical air masses. These climate patterns occur mainly in the regions of southern and southeastern Brazil. One consequence of these climate patterns is that southern Brazil has a humid climate with little or no marked dry season. The average annual precipitation is between 1400 and 2200 mm. The climate in southern South America is under influence of the Westerlies (Nimer, 1989; Weischet, 1996).

The main questions for this article are: What can postglacial pollen records tell us about the environmental history of South America? What has happened to the different South American ecosystems during postglacial times? How stable was vegetation and climate during the Holocene? What was the human impact on vegetation and environment?

Postglacial pollen records provide insights on past vegetation and climate changes from different regions of South America. Compared with Europe or North America, the paleovegetation and climate of South America is poorly studied. So far, probably not more than 200 postglacial pollen records are available for sites in South America (see the Global Pollen Database website). Most of them have been published during the last 20 years. This article provides an introduction to a limited number of pollen records. Several major ecosystems or regions from South America with detailed and well-dated representative pollen records have been selected for this overview. The radiocarbon ages cited here are in uncalibrated ¹⁴C ages (years BP).

Amazon Rainforest and Coastal Mangroves

The Amazon rainforest is the largest rainforest ecosystem in South America and covers an area of about 5 600 000 km². The Amazon Basin is low lying, with more than 1 000 000 km² below 100 m elevation. For example, the water level at Manaus, which lies 1200 km inland, is only 14 m a.s.l. As a consequence, the central and eastern part of the Amazon Basin and its vegetation as well as the coastal region with its mangroves and salt marshes must have been strongly influenced by the postglacial sea-level rise and dynamics.

The influence of Holocene sea-level changes on the Amazon Basin is documented by the Rio Curuá pollen record from the Caxiuanã forest reserve in eastern Amazonia (Figure 1; Behling and Costa, 2000). Four different Holocene paleoenvironmental intervals have been identified. First, there was a transition from an active to a passive fluvial system and a well-drained and diverse *terra firme* (unflooded upland) Amazon rainforest with very limited development of inundated

Figure 1 Summary pollen diagram from Rio Curuá. Modified from Behling H and Costa ML (2000) Holocene environmental changes from the Rio Curuá record in the Caxiuanã region, eastern Amazon Basin. *Quaternary Research* 53: 369–377.

forests (Várzea and Igapó forests) existed between >7990 and 7030 years BP. Figure 2 shows an inundated Várzea forest in Amazonia. Second, a sluggish river with a local *Mauritia* palm swamp and similar regional vegetation as before occurred between 7030 and 5970 years BP. Third, a passive river, forming shallow-lake conditions and with still-abundant *terra firme* forest, developed in the study region between 5970 and 2470 years BP, and finally, a blocked or impeded river with high water levels and marked increase of inundated forests occurred during the last 2470 years BP. Increased charcoal during this last interval suggests the first strong presence of humans in this region. Similar environmental changes, including the *Mauritia* palm swamp phase, have also been found in the Lago Calado record in the central Amazonia, suggesting that this environment was a regional phenomenon for low-lying areas in the Amazon Basin (Behling et al., 2001).

Based on the Lago do Crispim pollen record from the Amazon coastal area, mangroves first developed along the river close to the core site between 7550 and 6620 years BP (Figure 3; Behling and Costa, 2001). There is evidence that areas, originally covered by dense, tall coastal Amazon rainforest, were partly replaced by mangrove and some Restinga (coastal shrub and herbaceous vegetation) during the early Holocene. Decreasing *Rhizophora* (mangrove) pollen abundances document a retreat of mangroves, reflecting sea-level regression starting at around 7000 years BP. The marked reduction of mangroves near the lake indicates a lower relative sea level between around 6620 and 3630 years BP. During this

interval, a local *Mauritia/Mauritiella* palm swamp formed. Marked coastal environmental changes occurred at around 3630 years BP, driven by sea-level transgression. Mangroves expanded again and were close to the site. The local palm swamp was replaced by a Cyperaceae (sedge) swamp. Rainforest and coastal Restinga vegetation adjacent to the swamp were replaced by salt marshes as sea level rose. The Atlantic Ocean was close to the core site, but the site, which is only 1–2 m above modern sea level, was apparently never affected by marine incursions during the Holocene. Reduced mangrove vegetation, since ca. 1840 years BP, may be due to a slightly lower relative sea level or to human impact.

In western Amazonia, the Atlantic sea-level rise played a minor role. The pollen record from the lower terrace of Rio Caquetá in Colombia indicates that the terrace was poorly drained after 4000 years BP, as a result of higher river levels, probably due to higher precipitation rates in western Amazonia (Behling et al., 1999).

Amazon Rainforest and the Neighboring Savannas

Pollen records from the transition zone between Amazon rainforests and neighboring savanna ecosystems reflect the dynamic of the Amazon forest area (Behling et al., 2010). The pollen record from Laguna Loma Linda from the Llanos Orientales in Colombia is found in such a transition zone,

Figure 2 Seasonally inundated Várzea forest of the Amazon lowland in Brazil (Photo H. Behling).

which today is covered with Amazon rainforest (Figure 4; Behling and Hooghiemstra, 2000). Figure 5 shows a typical appearance of the Llanos Orientales in Colombia with grass savanna and gallery forest in the background. During the interval from 8700 to 6000 years BP, the vegetation of the region was dominated by grass savanna with only a few woody savanna taxa, such as *Curatella* (sandpaper tree) and *Byrsonima* (nance). Gallery forest along the drainage system was poorly developed. This is also evident from other pollen records from the central part of the Llanos Orientales. Compared to today, precipitation must have been significantly lower and seasonality stronger. During the interval from 6000 to 3600 years BP, rainforest taxa increased markedly, reflecting an increase in precipitation. Amazonian rainforest and gallery forest taxa were abundant, such as Moraceae/Urticaceae, Melastomataceae, *Alchornea*, *Cecropia* (trumpet tree), and *Acalypha* (copperleaf), while Poaceae (grasses) were reduced in frequency. From 3600 to 2300 years BP, rainforest taxa continued to increase; Moraceae/Urticaceae became very frequent, and Myrtaceae and *Myrsine* became common. Savanna vegetation decreased continuously throughout this interval. Pollen data from the central region in the Llanos Orientales indicate a marked increase of *Mauritia* palms since about that time. This indicates that precipitation was still increasing and that the length of the annual dry season was possibly shortened. From 2300 years BP onwards, grass savanna (mainly represented by Poaceae) expanded, and *Mauritia* palms became frequent. This reflects an increased human impact on the vegetation.

There is also evidence of late Holocene Amazon rainforest expansion in other regions, both north and south of the equator, reflecting a change to wetter climatic conditions with higher precipitation rates and longer wet periods since the mid-Holocene and especially during the late Holocene (Behling and Hooghiemstra, 2001). In southwestern Amazonia, there is evidence of Amazon rainforest expansion

Figure 3 Summary pollen diagram from Lago Crispim. Modified from Behling H and Costa ML (2001) Holocene vegetational and coastal environmental changes from the Lago Crispim record in northeastern Pará State, eastern Amazonia. *Review of Palaeobotany and Palynology* 114: 145–155.

Figure 4 Summary pollen diagram from Laguna Loma Linda. Modified from Behling H and Hooghiemstra H (2000) Holocene Amazon rain forest – Savanna dynamics and climatic implications: High-resolution pollen record Laguna Loma Linda in eastern Colombia. *Journal of Quaternary Sciences* 15: 687–695.

Figure 5 Savanna and gallery forest of the Llanos Orientales in Colombia (Photo H. Behling).

(Laguna Bella Vista and Chaplin, Bolivia) during the late Holocene, at least since 3000 years BP (Mayle et al., 2000). The expansion of the Amazon rainforest after 5460 years BP is also reported for the southeastern Amazon region (Behling, 2002a).

Caatinga in Northeastern Brazil

The modern vegetation in northeastern Brazil is primary Caatinga vegetation, which is subdivided into several physiognomic vegetation types, including grassland, xerophytic thorn shrub savanna, and shrub woodland. Pollen analytical studies have been carried out on a peat bog core located in the Icatu River Valley, within a system of stabilized sand dunes at the middle São Francisco River (10°24'S, 43°13'W) in northeastern Brazil (De Oliveira et al., 1999). The study region was dominated by the *Mauritia* palm during the early Holocene until about 4240 years BP, suggesting wetter climatic conditions than during the late Holocene. Between 8910 and 6790 years BP, there was a decrease in forest taxa and a gradual increase of Caatinga and Cerrado taxa. Later, the absence of pollen and spores in the core indicate semiarid conditions. Between about 6230 and 4540 years BP, there was a return of mosaic vegetation including gallery forest, Cerrado, and Caatinga, indicating the return of moister climatic conditions. After 4240 years BP, the increase in Caatinga and Cerrado taxa and the reduction of gallery forest taxa in the landscape reflect the establishment of the present vegetation and climatic conditions.

Cerrado, Semideciduous Forest, and Atlantic Rainforest of Southeastern Brazil

A pollen record has been studied from a 16 m long core from Lago do Pires, which today is located in semideciduous forest area, in a transition zone between the Atlantic rainforest to the east and the Cerrado to the west (Figure 6; Behling, 1995a). During the early Holocene interval from 9720 to 5530 years BP, the presence of Cerrado vegetation with some gallery forest indicates low precipitation and a dry season of about 6 months. Within this period, an interval from 8810 to 7500 years BP characterized by expanding gallery forest, suggests greater precipitation and a shorter dry season (6–5 months). From 5530 to 2780 years BP, the vegetation was characterized by extensive forest in the valleys, and Cerrado on hills, indicating higher precipitation and a dry season of about 5 months. From 2780 to 970 years BP, denser Cerrado vegetation on the hills and slopes suggests a dry season of 4–5 months. During the latest Holocene, the presence of closed semideciduous forest is indicative of modern climatic conditions. Markedly extended high-elevation grassland in the Serra do Mar coastal mountain range north of Rio de Janeiro indicates dry climatic conditions during the early Holocene until about 4910 years BP (Behling and Safford, 2010). Later, wetter conditions are indicated by reduced high-elevation grassland and the extension of Atlantic rainforest into higher elevation areas.

Araucaria Forest and Campos of Southern Brazil

Subtropical *Araucaria* forest is found mostly on the southern Brazilian highlands between latitudes 24° and 30° S at 1000–1400 m elevation. Several paleoecological studies from the *Araucaria* forest and Campos regions of the southern Brazilian highlands have been carried out in the last decade (Behling, 2002b). Figure 7 shows the *Araucaria* forest and Campos on the southern Brazilian highland. Data from the states of Paraná (Serra Campos Gerais: Behling, 1997), Santa Catarina (Serra do Rio Rastro, Morro da Igreja, Serra da Boa Vista: Behling, 1995b), and Rio Grande do Sul (Aparados da Serra: Roth and Lorscheitter, 1993; Cambará do Sul: Behling et al., 2004) have proved that extensive areas of Campos vegetation existed on the highlands through glacial, early, and mid-Holocene times. The dominance of Campos vegetation was attributed to cold and dry glacial conditions followed by warm and dry early Holocene climates. A dry season lasting probably about 3 months each year was characteristic for the early and mid-Holocene interval (Behling, 1997, 2002b). Initial expansion of *Araucaria* forests started by migration from the gallery forests along the rivers about 3000 years BP, which indicates a return to somewhat wetter climates. A marked expansion of *Araucaria* forests started on the highlands, replacing Campos vegetation in Santa Catarina State about 1000 years BP and in Paraná State (Serra Campos Gerais) about 1500 years BP, reflecting a very

Figure 6 Summary pollen diagram from Lago do Pires. Modified from Behling H (1995) A high-resolution Holocene pollen record from Lago do Pires, SE Brazil: Vegetation, climate and fire history. *Journal of Paleolimnology* 14: 253–268.

humid climate without a marked seasonal dry season. That burning is a strong factor controlling the dynamic between *Araucaria* forest and grassland during the late Holocene is shown by the record from the São José dos Ausentes region in Rio Grande do Sul State (Jeske-Pieruschka et al., 2010).

New data from the high-resolution Cambará do Sul record, which extends to 42 000 years BP, indicate that Campos vegetation prevailed on the southernmost highland during early and mid-Holocene times, but first small *Araucaria* forest populations migrated along river valleys to the study region (Figure 8; Behling et al., 2004). At the beginning of the Holocene, the species composition of the grassland changed, probably related to the Holocene warming. During the late Holocene interval at 3950 years BP, *Araucaria* forests expanded

and created a net of gallery forests along the streams. At that time, Campos was still the predominant vegetation, until 1140 years BP. Then, *Araucaria* forest trees, especially *Araucaria angustifolia* (Paraná pine) itself, replaced the Campos vegetation of the study region. For a certain interval between AD 1520 and 1780, *Weinmannia* trees became frequent in the *Araucaria* forest. Some years later, Poaceae and then Cyperaceae pollen increased, indicating that cattle had invaded the forest, an indication of increasing human impact. The introduction of exotic pines into southern Brazil about 180 years ago, the collection of tree fern trunks, the intensive logging of the *Araucaria* trees during the last 50–60 years, and the transformation of the original forest to a secondary forest are also registered in the pollen record.

Figure 7 *Araucaria* forest with Campos (grassland) on the southern Brazilian highland (Photo H. Behling).

Pampa of Argentina

The Holocene history of vegetation and climate of five Pampa sites are summarized by Prieto (1996). During the late early Holocene, grassland communities existed until 7000 years BP in the central part of the Pampa and until about 5000 years BP in the southwestern part of the Pampa. During the late Holocene, pollen data indicate vegetation that is similar to modern psammophytic (sand-adapted) and halophytic (salt-tolerant) communities of the southern Pampa, associated with communities characteristic of moister edaphic conditions. The drier climatic conditions changed to a subhumid-dry climate after 5000 years BP (Arroyo Sauce Chico, Cerro La China), about 4000 years BP (Fortín Necochea) and before 3000 years BP (Empalme Querandíes), with a trend to toward more humid conditions.

Figure 8 Summary pollen diagram from Cambará do Sul. Modified from Behling H, Pillar V, Orlóci L, and Bauermann SG (2004) Late Quaternary *Araucaria* forest, grassland (Campos), fire and climate dynamics, studied by high-resolution pollen, charcoal, and multivariate analysis of the Cambará do Sul core in southern Brazil. *Palaeogeography, Palaeoclimatology, Palaeoecology* 203: 277–297.

Andes in South America

The number of published pollen records from the Andes, especially from Colombia and Chile, is much greater than from the South American lowlands. Due to the great latitudinal extent of the Andes from 5° N to 55° S and the range's varied topographic features and altitudinal gradients, crossing different climatic zones, the recorded postglacial vegetation history is rather complex and cannot be generalized. Vegetation and climate patterns vary depending on location. Great vegetation changes occur within very short distances, for instance, from cloud forest with perhumid climatic conditions to a dry forest with long annual dry seasons and low rainfall rates.

The pollen records from the Colombian Andes, such as from Lake Fúquene (2580 m a.s.l.), indicate that glacial paramo (low vegetation growing above altitudinal treeline) and subparamo vegetation, indicative of cold and dry conditions, was replaced by Andean forest reflecting warm and humid conditions during the early Holocene. The onset of the drier climate prevailing today began in the middle Holocene (Vélez et al., 2003). Investigations on lake and peat sediments in the Cajas National Park (2°45'S, 79°10'W) of the western Andes in Ecuador indicate the occurrence of 11 drier and wetter phases during the Holocene (Hansen et al., 2003). Studies in the central Peruvian Andes from Laguna Baja (7°42'S, 77°32'W, 3575 m a.s.l.) document a decrease of pollen from Podocarpaceae (podocarp) and Urticales, reflecting an increase of warmer and wetter climatic conditions during the early Holocene. The first evidence for anthropogenic activities can be seen after 4000 years BP (Hansen and Rodbell, 1995).

Studies in the temperate forest region of the southern Andes at 40° S indicate that west of the Andes, a more extensive southern beech (*Nothofagus*) parkland existed during the early Holocene, and east of the Andes, there were a high number of steppe taxa, together with *Nothofagus dombeyi* type. On both sides of the Andes, a warmer and seasonally drier climate existed than is found there today (summarized by Markgraf in Grimm et al., 2001). Paleoecological studies on vegetations dynamics of the northern Patagonian rainforest in the Chonos Archipelago in southern Chile (44–46° S) document *Tepualia* and *Weinmannia* as important forest trees, reflecting a warmer climate between 10 600 and 6000 years BP than present. Later *Pilgerodendron* recovered and *Nothofagus–Pilgerodendron–Tepualia* forests occurred in that area until the present (Haberle and Bennett, 2004).

For further reading on post glacial pollen records in South American, see Behling (1998, 2002c), Behling and Hooghiemstra (2001), Grimm et al. (2001), and Markgraf (1993).

Northern Asia

A A Andreev, University of Cologne, Cologne, Germany
P E Tarasov, Free University of Berlin, Berlin, Germany

© 2013 Elsevier B.V. All rights reserved.

Introduction

The territory of northern Asia represents approximately 15% of the Earth's land surface and includes a wide variety of climatic and vegetation zones. It is situated between the Ural Mountains (ca. 60° E) in the west and the Pacific Ocean in the east (ca. 180° E), and between the Arctic Ocean in the north and ca. 47° N latitude in the south (**Figure 1**). The latter boundary corresponds to the southern limit of boreal coniferous forests in Kazakhstan and Mongolia. West of 90° E, the topography is relatively flat. Elevations of the West Siberian Lowland do not exceed 200 m, and hilly plains and low-elevation (up to 1500 m) mountains occur in northern Kazakhstan. East of 90° E, the topography is more complex. Lowlands occupy a 50–600-km-wide band along the Arctic coast, while central and southern regions consist of high plateaus and mountains above 1000 m. The highest elevations occur in the Altai (4506 m) and Hangai (3905 m) mountains and on the Kamchatka Peninsula (4750 m).

The climate of northern Asia is cold and continental. A strong Siberian anticyclone controls winter weather. The mean January temperatures vary from -16°C in the south to -48°C in the interiors of east Siberia. The absolute temperature minimum registered in the Verkhoyansk Mountains is -68°C . July temperatures (T_{VII}) decrease northward from ca. 20°C to less than 4°C . More than 65% of the annual precipitation (P) falls during the warm season, when the weather is controlled by the westerlies and the Pacific monsoon. P reaches 600 mm in the Ural Mountains and 1000 mm in the Far East. In Kazakhstan, central Yakutia, and Mongolia, situated far from oceanic influence, P is less than 300 mm.

The spatial distribution of vegetation shows the clear influence of climate. In the mountains, it is complicated by altitude and slope orientation. Various moss, grass, dwarf shrub, and shrub tundra types (tundra zone) occupy arctic lowlands and the upper belt of the mountains and high plateaus. Southward, this is gradually replaced with boreal cold deciduous and evergreen conifer forests (taiga) dominated by larch (*Larix*), Siberian spruce (*Picea obovata*), Scots pine (*Pinus sylvestris*), Siberian pine (*P. sibirica*), and fir (*Abies sibirica*). Broad-leaved trees are represented mostly by cold- and drought-resistant birch (*Betula pubescens* and *B. pendula*) and aspen (*Populus tremula*). Temperate deciduous taxa, such as elm (*Ulmus*) and lime (*Tilia*), play minor roles in the modern vegetation. Wych elm (*U. glabra*) and Siberian small-leaved lime (*T. sibirica*) trees occur sporadically in the West Siberian Lowland and Altai Mountains, and Siberian elm (*U. pumila*) may grow in the floodplain forests south of Lake Baikal.

Since **Dokturovskii and Kudryashov (1923)** provided pollen identification keys for the main arboreal taxa in Russia, scientists from the former Soviet Union published numerous articles and monographs reconstructing postglacial changes in northern Eurasian vegetation by means of pollen analysis; for a comprehensive synthesis, see **Neishtadt (1957)**, **Khotinskii**

(1977), **Grichuk (1984)**, **Peterson (1993)**, and **Velichko et al. (1997)**. The collapse of the Soviet Union intensified the level of international cooperation, resulting in the appearance of extensive compilations of existing northern Eurasian pollen data (e.g., **Edwards et al., 2000**; **Gunin et al., 1999**; **Tarasov et al., 1998**; **Williams et al., 2011**; and references therein) and in the publication of new high-resolution and better dated pollen records. Since the late 1970s, there has been a rapid increase in the number of published pollen diagrams from northern Asia. **Khotinskii (1977)** had used 26 pollen sequences to reconstruct the Holocene vegetation history of northern Asia, but now, there are ca. 200 records archived in the global and European pollen databases.

In this article, the authors review the postglacial vegetational and climate changes in northern Asia based on pollen records with reliable chronologies, rather than attempting to synthesize a complete northern Asia-wide picture of postglacial environmental changes, which requires further refinement of site spatial coverage and chronologies. Unless otherwise indicated, dates in this discussion are in calendrical-equivalent (calibrated) years before present.

The Ural Mountains

The pollen record from Lake Lyadhej-To ($68^{\circ}15'\text{N}$, $65^{\circ}45'\text{E}$, 150 m a.s.l., site 1 in **Figure 1**), situated in the shrub–herb tundra zone at the NW rim of the polar Ural Mountains, provides information on the Holocene environmental history of this area (**Andreev et al., 2005**). Pollen of sedges (Cyperaceae), grasses (Poaceae), and dwarf birches (*Betula* sect. *Nanae*) (**Figure 2**) from the lowermost sediments suggests sparse tundra-like vegetation around the lake ca. 10.7–10.55 cal ka BP. Approximately 10.55–8.8 cal ka BP birch forest with some shrub alder grew around the lake, reflecting the warmest climate of the Holocene with T_{VII} 11–13 °C. Pollen records from the adjacent areas also reflect a major spread of birch at that time in what is now treeless tundra (**Andreev et al., 2005** and references therein). Higher values of dwarf birch and sedge pollen and significantly lower pollen concentrations point to climatic deterioration during 8.8–5.5 cal ka BP. Birch forests completely disappeared from the lake's vicinity at about 6 cal ka BP, and shrub and herb tundra communities became dominant in the regional vegetation after about 5.5 cal ka BP. Pollen-based reconstruction suggests significant cooling between 5.5 and 3.5 cal ka BP with T_{VII} up to 8 °C, leading to establishment of a shrub–herb tundra similar to the modern vegetation.

West Siberia

Pollen diagrams from the West Siberian Lowland are quite numerous (e.g., **Volkova and Mikhailova, 2002** and references

Figure 1 Map of northern Asia showing the location of cited sites.

Figure 2 Percentage palynological diagram of selected taxa from Lake Lyadhej-To record. Pollen zonation is according to Andreev et al. (2005).

therein). The Pur-Taz peat section from the flat watershed between the Pur and Taz Rivers ($66^{\circ}42'N$, $79^{\circ}44'E$, site 2 on Figure 1) is one of the better-studied sequences from the forest-tundra transitional zone with Siberian larch (*L. sibirica*) as a dominant tree. The section yielded pollen and macrofossil records of vegetation and climate history at the Arctic treeline ca. 10.4–5.1 cal ka BP (Peteet et al., 1998). The presence of

larch and tree birch pollen in the Late Glacial/early Holocene indicates that regional summer temperatures were warm enough to support the growth of trees. An increase in spruce pollen between 10 and 5.1 cal ka BP suggests a movement of spruce into the north as the result of warmer-than-present early Holocene climate. Quantitative pollen-based climate reconstruction (Andreev and Klimanov, 2000) shows that the

warmest interval (T_{VII} 2.5 °C higher than today) occurred in the area ca. 6.8–5.6 cal ka BP. This is approximately the same time as the dominance of spruce (*Picea*) macrofossils at the Pur-Taz site. The decrease in evergreen conifer tree pollen and macrofossils registered in the uppermost peat layer suggests a late Holocene shift toward colder environments similar to today (Peteet et al., 1998).

Pollen data from the Salym–Yugan area (60°10'N, 72°50'E, site 3 in Figure 1) help to trace the Holocene vegetation history in the southern part of West Siberia (Pitkänen et al., 2002). The modern vegetation of the area consists of forests (mainly Scots pine) and open mire communities. Pollen data suggest that open sedge associations dominated the vegetation between ca. 10.9 and 9.9 cal ka BP and trees, such as larch, spruce, and birch, were poorly represented in the regional vegetation. On the other hand, the pollen sequence from Bugristoye (58°15'N, 85°20'E, site 4 in Figure 1) demonstrates that larch (up to 40%), spruce (up to 25%), and birch (up to 60%) absolutely dominated the pollen spectra as early as 11.4–10.8 cal ka BP, suggesting significant afforestation of the Ket'–Chulym watershed at that time (Blyakharchuk and Sulerzhitsky, 1999). This conclusion agrees with other West Siberian pollen data (Volkova and Mikhailova, 2002). In the Salym–Yugan area, birch and pine forests became established shortly after 9.9 cal ka BP, but spruce was rather abundant until about 4.3 cal ka BP, while the Bugristoye record demonstrates a decrease in spruce abundance shortly after 6.3 cal ka BP, reflecting climate deterioration. Peat accumulation at the Bugristoye site stopped shortly after ca. 4 cal ka BP. After 4 cal ka BP, modern birch–pine forest dominated the vegetation in southern West Siberia, although large regions were covered with open mire vegetation.

Kazakhstan

Reliable records of the Holocene vegetation and climate dynamics in the vast area of northern and central Kazakhstan

were not available until the 1990s (Kremenetski et al., 1997 and references therein). Ozerki swamp (50°25'N, 80°28'E, 210 m; site 5 in Figure 1) located in the Irtysh River valley provides the most complete postglacial pollen record from the forest–steppe transition zone in northern Kazakhstan. In this area, modern steppe vegetation is dominated by grasses and *Artemisia* (sage) species and Chenopodiaceae (goosefoot family) and *Ephedra* (Mormon tea) grow on compacted soils (Tarasov et al., 1997). High summer temperatures and low precipitation limit the spread of patchy birch and pine forests to the river valleys and low mountains. The Ozerki record suggests that an oxbow depression currently occupied by the swamp was filled with water at about 15 cal ka BP, suggesting amelioration of the very dry and cold 'glacial' climate. The lowermost pollen zone (Figure 3) reveals the highest percentages of nonarboreal pollen (NAP) taxa (up to 85%), suggesting rather dry environments and steppe vegetation. However, the occurrence of *Hippophae* (sea-buckthorn), spruce, and larch pollen in this pollen zone can be interpreted as the spread of sea-buckthorn shrubs and trees along the Irtysh River between 15 and 12 cal ka BP. These taxa can be found today in the Altai Mountains, southeast of the study site. Since 12 cal ka BP, the vegetation composition has been similar to that found today in the Kazakhstan steppe. Around 8.5 cal ka BP, birch pollen exceeded 70%, suggesting expansion of birch forest in the area and probably wetter-than-present climate conditions. After 6.5 cal ka BP, the pollen spectra reflect the spread of pine from the south Ural and West Siberia to northern and central Kazakhstan. Regional pollen data (Kremenetski et al., 1997; Tarasov et al., 1997) suggest that Scots pine was already established in northern Kazakhstan by 7 cal ka BP, but did not reach its modern limit in central Kazakhstan until after 2 cal ka BP. Thus, the afforestation of the steppe zone reached a maximum only during the last millennium (Tarasov et al., 2005). Because none of these changes in vegetation can be attributed to human activities, a climatic explanation should be invoked.

Figure 3 Percentage palynological diagram of selected taxa from Ozerki Swamp record. Pollen zonation is according to Tarasov et al. (1997).

Figure 4 Percentage palynological diagram of selected taxa from Lake Levinson-Lessing record. Pollen zonation is according to Andreev et al. (2003).

Central Siberia

Environmental changes since about 32 ^{14}C ka BP from northern central Siberia are recorded in the sediments of Levinson-Lessing Lake (74°28'N, 98°38'E, site 6 in Figure 1) in the northeastern Taymyr Peninsula (Andreev et al., 2003). The lake is situated in the tundra zone. Pollen spectra (Figure 4) contain large amounts of herbaceous taxa in the lower part of the record, including grasses and sage, reflecting severe continental climate and scarce, steppe-like vegetation until ca. 13.7 cal ka BP. Dwarf shrub and sedge tundra vegetation had limited coverage and survived only in wet habitats. Dramatic increases in shrub birch and willow pollen and in total pollen concentration, associated with a significant decrease in sage, grasses, and other herb taxa pollen, reflect a climatic amelioration after 13.7 cal ka BP corresponding with the Allerød in Europe. This was followed by an increase in herbaceous taxa pollen, likely indicating a cooling associated with the Younger Dryas (YD). Pollen spectra from the Pleistocene/Holocene transition dated to ca. 11.5–11.2 cal ka BP reflect a shift in vegetation from herb-dominated to shrubby birch–willow tundra. Shrub alder occurred in the area approximately 10 cal ka BP and disappeared after 3.8 cal ka BP. Dwarf birches, which were broadly distributed in the region during the early and middle Holocene, also almost disappeared after 3.2 cal ka BP, when the vegetation became similar to the modern herb tundra. Quantitative paleoclimatic interpretation of the pollen spectra suggests that T_{VII} was 2–4 °C higher than the present during the early Holocene and became similar to the present after 6.3 cal ka BP.

A continuous pollen record from Lama Lake, from western Taymyr (69°32'N, 90°12'E, site 7 in Figure 1), provides detailed environmental information for the Late Glacial and Holocene in central Siberia (Andreev et al., 2004). At present, the vegetation cover in the region varies, depending on

altitude: dense spruce–larch–birch taiga dominates at the lower elevations, while shrub and herb tundra cover the higher mountains. The pollen data suggest that scarce, steppe-like plant communities dominated the vegetation around the lake during the Late Glacial (Figure 5). Tundra-like communities with arctic dwarf shrubs, sedges, and Brassicaceae (cabbage family) species grew in wetter habitats. Reconstructed climate fluctuations may be correlated with the Bølling/Allerød warming and YD cooling. The Late Glacial/Preboreal transition occurred at about 11.5 cal ka BP. It is characterized by a significant increase in dwarf birch and willow pollen accompanied by a relatively high NAP content, suggesting a broad distribution of shrubby and meadow associations. Abundant spores of *Sphagnum* (peat moss) and Polypodiaceae (polypody fern family) indicate wet habitats around the lake. High contents of larch and alder pollen in the early Holocene sediments indicate that larch occurred in the area as early as 11 cal ka BP, while shrub alder came to the area 200 years later. Spruce did not reach the area before about 10.3 cal ka BP. The spruce pollen content and the total pollen concentration increased dramatically in the deposits dated to ca. 10.1–8.8 cal ka BP, indicating the broad distribution of spruce under warm summer conditions. The paleoclimatic reconstruction from the Lake Lama pollen record suggests that T_{VII} during the early Holocene was ca. 1.5–3.5 °C above modern values. Other paleobotanical records (Andreev et al., 2004 and references therein) also confirm the broad distribution of spruce in the western Taymyr during this interval. A gradual decrease in spruce pollen in the sediments younger than 5.2 cal ka BP reflects a gradual deterioration of the regional climate. A significant increase in birch pollen percentages in the upper part of the Lake Lama core likely mirrors the increased role of birches in the local forests after 2.5 cal ka BP. The sharp decrease in the arboreal pollen (AP) content and the increase in sage pollen content at 30–15 cm depth may be correlated with the Little Ice Age.

Figure 5 Percentage palynological diagram of selected taxa from Lake Lama record. Pollen zonation is according to Andreev et al. (2004).

East Siberia

The pollen record from Dolgoe Lake, situated in the lower Lena River (71°52'N, 127°04'E, site 8 in Figure 1), is valuable for the reconstruction of paleoenvironments in the present-day larch forest-tundra, dominated by dwarf birch and shrub alder (Pisaric et al., 2001). Sedges, grasses, and sages dominate pollen spectra deposited shortly before 14.5 cal ka BP, reflecting open vegetation with only a sparse cover of herbs and grasses around the lake. An increase in shrub birch pollen higher in the sequence points to the establishment of shrub birch tundra between 14.5 and 13 cal ka BP. A sharp decrease in shrub birch pollen and rise in herbaceous pollen percentages between 13 and 11.5 cal ka BP suggest a return to a more open vegetation cover. The timing of this vegetation shift is synchronous with YD oscillation. After 11.5 cal ka BP, shrub birch pollen percentages rise, associated with the onset of the Holocene. Around 11 cal ka BP, birch was replaced as the dominant taxon by alder, likely by shrub alder (*A. fruticosa*). The increase in larch pollen percentages after 9.5 cal ka BP, coupled with the presence of larch in the stomata and macrofossil records, suggests that it grew north of Dolgoe Lake between 9.5 and 3.8 cal ka BP. At about 7.6 cal ka BP, spruce increased in abundance in the pollen record. Today, spruce grows 350 km to the south. However, the presence of its pollen and stomata in the lake record indicates that spruce occurred in the local vegetation between 7.6 and 3.8 cal ka BP, providing evidence of a considerable northward range extension in the mid-Holocene. Low AP percentages and AP concentrations in the sediments dated younger than 3.8 cal ka BP suggest a change in the environment and a shift from predominantly woodland vegetation to the modern shrub tundra with isolated larch stands.

Khomustakh Lake (63°43'N, 129°22'E, site 9 in Figure 1) has been selected as a key site for the study of postglacial vegetation in the central part of eastern Siberia (Velichko et al., 1997). At present, pine forests occupy sandy soils in the area, whereas clayey soils are occupied by larch forests. Sedimentation and pollen accumulation in the lake started about 12 cal ka BP (Figure 6), probably as a consequence of the Allerød climate

amelioration. Rather high levels of dwarf birch, sage, grasses, and other herbaceous pollen taxa point to their important role in the local vegetation, codominant with open herb and shrub tundra-like vegetation. A subsequent increase in sage and other herb pollen contents likely reflects the YD cooling. The transition to the Holocene is dated to about 11.5 cal ka BP (see International Stratigraphic Chart website) and is marked by a dramatic increase in tree birch pollen. During the Preboreal interval, birch dominated the vegetation; however, the permanent presence of larch in the pollen spectra indicates that it also was an important component in the local forests until about 6.8 cal ka BP. After 7 cal ka BP, Scots pine migrated to the area and quickly occupied sandy habitats in central and southern Yakutia. Quantitative climate reconstruction based on the Khomustakh pollen record suggests that T_{VII} was up to 1.5 °C warmer than the present in the middle Holocene, causing degradation of the permafrost and facilitating the spread of pine. Since 6.8 cal ka BP, forests composed of pine started to dominate in these regions. Recent paleoecological studies (Müller et al. (2009) site 11 and Werner et al. (2010) site 10 in Figure 1) reveal similar vegetation changes.

South Siberia

This area is extremely important from the paleobotanical viewpoint, because it appears likely that, during the last glaciation, the hills and mountains of southern Siberia provided refuge for the tree species that make up the present boreal forest belt (Grichuk, 1984). Postglacial pollen records from this region mainly come from Lake Baikal and its vicinity (Demske et al., 2005; Tarasov et al., 2002; and references therein). The pollen diagram (Figure 7) from Lake Kotokel (52°46'N, 108°46'E, 458 m, site 12 in Figure 1), situated near the eastern coast of Lake Baikal, illustrates changes in vegetation since the last glacial (Bezrukova et al., 2010; Tarasov et al., 2002, 2009). At present, the lake is surrounded by boreal forest dominated by Scots and Siberian pine, larch, and birch trees. Stands of shrub pine (*P. pumila*), birch, and alder are abundant in the

Figure 6 Percentage palynological diagram of selected taxa from Lake Khomustakh record. Pollen zonation is according to Velichko et al. (1997).

Figure 7 Percentage palynological diagram of selected taxa from Lake Kotokel record. Pollen zonation and quantitative changes in woody cover percentages within a 21×21 km window are according to Bezrukova et al. (2010).

mountain tundra belt, beyond the continuous treeline. The interval prior to about 14.7 cal ka BP was very dry and cold, as indicated by high percentages for steppe herbs and pollen from woody plants below 5% (Figure 7). Since that time,

climate became warmer and wetter, as marked by a gradual increase in tree and shrub pollen percentages and in woody coverage to 20–30% ca. 14.5–14 cal ka and ca. 13.3–12.8 cal ka BP. These two intervals correspond to the Meiendorf and

Allerød interstadials, which were interpreted as part of the undivided Bølling/Allerød interstadial in the Baikal region (Bezrukova et al., 2005). The increase in tundra shrubs and sedge pollen percentages indicating the YD in the region between 12.7 and 11.65 cal ka BP is in agreement with the formal definition and dating of this cold oscillation based on the Greenland NGRIP ice core records. The maximal spread of the taiga communities in the region is associated with a warmer and wetter climate than the present prior to ca. 7 cal ka BP. This was followed by a wide spread of Scots pine, indicating the onset of modern environments. Since that time, pollen spectra show very little change, likely indicating that vegetation composition and distribution patterns became similar to those of today.

Mongolia

A comprehensive synthesis of pollen and plant macrofossil records from Mongolia is presented by Gunin et al. (1999). That monograph presents reconstructions of Late Glacial and Holocene vegetation dynamics. Several other papers discuss vegetation and environmental changes at the regional scale (Fowell et al., 2003; Rudaya et al., 2009; Tarasov et al., 2000, 2004; and references therein). A ^{14}C -dated pollen record from Hoton–Nur (48°40'N, 88°18'E, 2083 m), a large freshwater lake in the northern Mongolian Altai (site 13 in Figure 1), spans the whole Holocene (Figure 8). Pollen concentration and preservation in the lower part of the 9.2-m record from Hoton–Nur was extremely poor, suggesting severe 'glacial' conditions and scarce vegetation around the lake. Pollen spectra of the Ho-3 pollen zone showed relatively high frequencies of pollen of Arctic–alpine taxa, including shrub alder and birch, sedges, and grasses (Gunin et al., 1999). This suggests a slight amelioration of the Late Glacial climate and the spread of tundra vegetation at higher elevations and river valleys. However, high percentages of sage and Chenopodiaceae pollen in the Ho-3 zone suggest that before about 10.1 cal ka BP, the

dominant vegetation close to the lake was dry steppe (Tarasov et al., 2000). In the Ho-2 pollen zone dated to ca. 10.1–4.5 cal ka BP, the dominance of spruce, pine (most probably Siberian pine), and larch pollen likely indicates that patches of boreal conifers played a more important role in the local vegetation than they do today. Expansion of boreal evergreen conifers in the region would require noticeably wetter conditions than those prevailing today. However, the presence of relatively high percentages of herbaceous pollen suggests an open mosaic of forest–steppe-like vegetation. Pollen from the uppermost zone demonstrates that vegetation around the lake reflected drier conditions and became similar to the modern steppe with small forest patches of larch and Siberian pine, taxa that are less sensitive to water stress than spruce. Quantitative reconstruction of the Holocene vegetation and climate dynamics in the semiarid Mongolian Altai (Rudaya et al., 2009) suggests that boreal woodland replaced the primarily open landscape of northwestern Mongolia at about 10 cal ka BP in response to a noticeable increase in P from 200–250 to 450–550 mm. A decline of the forest vegetation and a return to a predominance of open vegetation types occurred after 5 cal ka BP when P decreased to 250–300 mm.

Northeastern Asia

A sediment core from the Smorodinovoye Lake in the Upper Kolyma region (64°46'E, 141°06'E, site 14 in Figure 1) provides a ca. 27 cal ka record of vegetation changes from northeastern Siberia (Anderson et al., 2002). High percentages of grass and sage pollen and the variety of xeric taxa such as rock spike moss (*Selaginella rupestris*) (Figure 9) suggest that open grass–sage vegetation dominated the landscape during the Late Glacial. A dramatic rise in birch percentages around 12.8 cal ka BP implies rapid establishment of shrub tundra in response to postglacial warming. Birch–willow tundra dominated the vegetation between ca. 12.8 and 11.8 cal ka BP. A decline in shrub birch and an increase

Figure 8 Percentage palynological diagram of selected taxa from Lake Hoton–Nur record. Pollen zonation is according Tarasov et al. (2000).

Figure 9 Percentage palynological diagram of selected taxa from Lake Smorodinovoye record. Pollen zonation is according to Anderson et al. (2002).

in grass and sage pollen percentages indicate that the vegetation reverted to herb-dominated tundra shortly after 11.8 cal ka BP. The vegetation change suggests that summer temperatures and *P* became lower than during the previous interval (12.8–11.8 cal ka BP), but not as extreme as during the Late Glacial. This short-term episode most likely represents the YD cooling. An increase in birch and willow pollen from ca. 11.3–9.5 cal ka BP suggests that shrub tundra again became dominant with the onset of the Holocene. Alder percentages increased at ca. 11 cal ka BP, but alder was not widespread until about 10 cal ka BP. The presence of a larch needle and single larch pollen grains indicates that larch was present in the area as early as about 10.9 cal ka BP. During 9.5–7 cal ka BP, birch and alder continued to dominate the pollen assemblage, indicating that shrub tundra with isolated larch trees dominated the vegetation. Shortly after 7 cal ka BP, shrub pine occurred in the area, as suggested by the composition of the pollen assemblages. Pollen spectra suggest that since that time, birch, alder, and heath shrubs were common on the landscape and, along with the dwarf Siberian pine, were abundant in the understory of the larch forest. High shrub tundra, dominated by dwarf Siberian pine, also became established on the mountain slopes above the altitudinal tree limit.

Conclusions

Generally, the pollen records discussed above demonstrate spatially and temporally coherent patterns of environmental changes. Open sage- and grass-dominated communities were widespread in northern Asia during the Late Glacial. A significant increase of shrub pollen registered in several of the records may be correlated with the Bølling/Allerød warming, ca. 13.7 cal ka BP. The subsequent increase in NAP reflects the cooling/drying of the YD interval. Many records show that the Late Glacial/Preboreal transition occurred at about 11.5 cal ka BP and was characterized

by a significant increase in birch, shrub alder, and willow pollen and in woody cover percentages (Tarasov et al., 2007; Williams et al., 2011). Records from geographically different sites demonstrate different patterns of vegetation changes connected with local environmental conditions and migration history of the arboreal species. However, the interval from ca. 10.5 to ca. 8.8 cal ka BP was the warmest postglacial episode (the Holocene climatic optimum) in the arctic regions of northern Asia (e.g., Andreev et al., 2005; Velichko et al., 1997). In contrast, records from the more southerly sites, within the boreal forest and forest-steppe zone, show an early Holocene climate amelioration that is less pronounced than that of the middle Holocene. The explanation of these phenomena can be found in the unequal influence of the lower-than-present sea level and higher-than-present summer isolation during the Late Glacial and early Holocene.

Introduction

Pollen records retrieved from sediment accumulations provide insights into past vegetation and thus past habitat and environment. Not surprisingly, pollen records from the current interglacial (the Holocene) occur more abundantly and have been subjected to more detailed study than records from any other interval. This article reviews some of the key issues raised by pollen records from the postglacial interval in northern Europe. For the purposes of this work, the postglacial interval is considered to be the time from the onset of full interglacial conditions at the start of the Holocene until the present, and northern Europe includes the Scandinavian countries.

Terrestrial pollen records are usually retrieved from waterlogged sedimentary environments such as peat bogs and lakes; records from such environments are both likely to be well preserved and to have the best stratigraphic integrity. These sedimentary systems form in low lying, wet parts of the landscape and thus are most common in areas with variable topography and/or impermeable substrates. One of the legacies of glaciation in northern Europe is a landscape with many suitable places for initiation of sediment accumulation, with a wide range of depressions formed by processes such as scour and erosion of bedrock, or deposition of moraine dams and of undulating till fields which include features such as kettle holes. Fluvial environments also provide preservation opportunities, from paleochannel infilling and deposition in oxbow lakes to the development of floodplain-wide wetlands such as alder carrs. Other suitable preservation locales are formed by coastal processes (e.g., sea-level isolation basins, salt marsh sediments). Many important records have also been retrieved from peat deposits such as raised mires and blanket peat; the formation of these sedimentary archives is controlled primarily by climate factors and the presence of impermeable substrates allowing waterlogging rather than underlying topography, but initiation of peat accumulation often postdates the end of the glacial interval by several thousand years giving only partial records of the postglacial (Barber, 1993).

Despite the range of sediment-forming contexts available, site distribution is patchy. Sites are not distributed randomly across the region, and so pollen records are not available from all landscapes or from all site types within one landscape area. For example, unglaciated parts of southern England have produced far fewer complete postglacial pollen records than the formerly glaciated uplands of the Lake District in northwest England. Lack of data for some parts of the landscape is therefore still an important limitation, although less so in northern Europe than in most of the rest of the world. The concentration of population in northern Europe has led to a concentration of universities and other research institutes that can support palynological research and thus ensure that the local area is well studied; this too can lead to patchy coverage. For example, in Scandinavia, more records are available for the relatively

densely populated south than for the geographically larger but less settled central and northern areas. Wetlands and lakes are also under pressure from human population, through draining and peat extraction, exposing sites that may contain good pollen records and adding urgency to their collection. In places this population density leads to a serious loss of pollen records, especially in lowland agriculturally productive areas where extensive drainage of wetlands and conversion to agricultural uses has substantially reduced the availability of sites that have the potential to yield pollen records.

A selection of European pollen records is curated in the European Pollen Database (EPD), and some of the data can be accessed through the NOAA website or directly through the EPD website. The overview of pollen records for different parts of Europe (mainly northwest Europe) presented in the report on International Geoscience Program project 158B (Berglund et al., 1996) does not cover the whole area, yet at least some of these 'pollen gaps' are due at least in part to an absence of sites rather than a lack of research activity. There are approximately 300 pollen records from northwest Europe archived in the EPD.

Broadly, the postglacial pollen record from northern Europe is a record of the reestablishment of forest biomes in areas occupied during the glacial interval by arctic and subarctic tundra and steppe communities, or by ice. The other key feature of the postglacial interval is the unprecedented spread of human activity both in space and in intensity, which forms part of the argument over nomenclature for the present interglacial. The older British term Flandrian (and other regional terminologies) treats the present postglacial interval as just the latest in a sequence of Pleistocene interglacials (Hyyvärinen, 1978), whereas strictly speaking the term 'Holocene' treats the postglacial as the beginning of a new geological epoch of equivalent status to the Pleistocene (see International Stratigraphic Chart website).

Chronologies

Before the development and application of radiocarbon dating in the 1950s, postglacial pollen records were correlated with each other largely on the basis of the arrival of particular tree species or changes in the pollen assemblage or peat structure which were believed to represent synchronous responses across the region to Holocene climatic events. The Blytt-Sernander scheme divided the Holocene into four broad climatic intervals primarily on the basis of variations in peat stratigraphy and associated plant macrofossils (Von Post, 1916). It was widely applied to pollen records and used as a tool to correlate records across northern Europe (see *History of Quaternary Science; Table 1*). The terminology associated with this scheme (e.g., 'Atlantic period') is still encountered widely in allied literatures and textbooks. In peatlands, periods of changed decay conditions and accumulation rates marked by different colors and

Table 1 The Blytt–Sernander scheme and the commonly used European pollen zone numbering system based on it

<i>Blytt–Sernander zone name</i>	<i>Inferred climate</i>	<i>European pollen zone number</i>	<i>Pollen record characteristics</i>
Sub-Atlantic (most recent)	Cold and wet, oceanic	IX	Climatic deterioration, spread of bogs
Sub-Boreal	Warm and dry, continental	VIII	Mixed-oak forest; some 'late arrival' species occur, for example, beech, hornbeam
Atlantic	Warm and wet, oceanic	VII	Mixed-oak forest: lime and alder arrive at start
Late Boreal	Warm and dry	VI	Oak, elm arrive
Early Boreal	Warm and dry	V	Large amounts of hazel Pine dominance

preservation conditions of peats were also attributed to a response to these major climate changes.

Radiocarbon dating showed the flaws in this simple assumption of synchronicity, but also opened up new areas of investigation. One of the attractions of researching postglacial pollen records is the ready applicability of radiocarbon dating of the organic components to establish a chronology, which enables correlation between sites within regions, with archaeological records, and with other evidence from the wider landscape. However, radiocarbon dating is not without its own challenges, and each radiocarbon-based chronology has associated errors and areas of uncertainty. Tephrochronology offers the possibility of more confident age correlation between sites at some points in the past, but the patchy distribution of distal tephra from distant (mainly Icelandic) sources means that tephrochronology cannot be a replacement for radiocarbon dating in northwest Europe.

Dating shows that the basal age of pollen records across northern Europe varies. This is due in part to the time-transgressive nature of glacial retreat, but the establishment of full interglacial conditions does not always correlate with

the beginning of an organic sedimentary record. For example, the onset of peat formation in upland and exposed coastal locations appears to have been highly time transgressive, depending as it does on a combination of climatic conditions, soil type and permeability, and catchment hydrologic regime. In some locations, the timing of peat development appears to be strongly related to human activity and changes in the tree cover and erosion regimes, and in others, the timing of the creation and abandonment of paleochannel features suggests similar controls.

The Postglacial Pollen Record

Figure 1 is a schematic composite pollen diagram for the postglacial interval in northwest Europe showing the main features characteristic of such diagrams. In this section, some of the key issues raised by the study of diagrams from across the region are discussed, which show strong geographical variation in both the timing and the relative importance of events.

Figure 1 Schematic pollen record from the postglacial of northern Europe. Zone boundaries indicate the approximate limits of the Blytt–Sernander climate zones (see Table 1) in this particular case.

Recolonization by Forest

One area of research opened up by the radiocarbon chronology was the investigation of the rates and routes of the reinvasion of northern Europe by temperate tree species in the first part of the postglacial interval. Tree species appear to have survived glacial periods in refugia in southern regions and on the exposed continental shelf. Recent research has also begun to search for 'cryptic refugia,' microclimatic 'pockets' in the north European plain where some temperate species survived or were able to colonize during Late Glacial times (Stewart and Lister, 2001), allowing rapid expansion as soon as local conditions were suitable.

By using sites with radiocarbon chronologies, it is possible to map the distribution of pollen of particular taxa across Europe at specific points in time (creating isopoll maps) and thus reconstruct their changing distributions. Huntley and Birks (1983) compiled an atlas documenting the spread of tree taxa across Europe during the Late Glacial and postglacial. More recent research has tended to either develop detailed isopoll maps for smaller parts of Europe (Prentice, 1983), or to focus on reconstruction of a single point in the past (e.g., the BIOME 6000 project).

Macrofossil evidence provides an important check and correction on the maps produced, especially at range limits or for taxa that are less well represented in the pollen record. Phytogeography, studying the present-day distribution of genetic markers across a species range, offers additional evidence for migration routes, and the extraction of ancient DNA from subfossil plant remains including pollen grains, seeds, and other plant parts offers opportunities to test reconstructed patterns of population dynamics.

Isopoll mapping shows that taxon response to climate amelioration and the opening up of new potential habitat in northern Europe was essentially individualistic (Huntley and Prentice, 1993). The arrival of the various tree taxa was not synchronous and cannot be correlated across regions (although the assumption of synchronicity is still widely applied within defined areas). In formerly glaciated areas, forest biomes reestablished at the end of a primary succession sequence, in which pioneering mosses and herbs gave way to pioneering shrubs and trees. Different plant species played the dominant roles in this process, across different parts of Europe (Huntley, 2009). The process of invasion of a new species into already established woodland is less clearly understood than initial invasion. Studying the process probably requires stand-scale resolution data, which are not always available. Most postglacial pollen records come from relatively large basins (diameter measured in 10s of meters or more) and therefore reflect a larger area of landscape than the stand (see Jacobson and Bradshaw, 1981). Comparison with other interglacials opens up questions about the reasons for the different timing and pattern of tree invasion and expansion in each interglacial, suggesting that chance factors may be as important as climatic and biological variations. Isopoll maps also provide information for the study of changes in range limits of taxa during the postglacial and changes in treeline composition and position, which can elucidate a climatic signal.

The Wildwood: What Is the Natural Vegetation of Northern Europe?

According to bioclimatic models, northern Europe should largely be tree covered today. The relative openness of the

landscape actually observed is generally attributed to millennia of human activity, and one research focus has been reconstructing and mapping the latest stage of the 'WildWood' (Rackham, 2000), the hypothesized natural forests of northern Europe, before the impact of agricultural activity (Kaplan et al., 2009). These maps are of particular interest as a guide for conservation and landscape restoration activities. This approach assumes, however, that the main anthropogenic impact on vegetation occurred after the widespread adoption of agriculture.

A date of around 6000 cal years BP is often used for these studies. This just predates most records of arable and pastoral agriculture in northwest Europe (Bonsall et al., 2002; Gkiasta et al., 2003). However, it is toward the end of the 'Atlantic' period, which is argued to represent 'better' climatic conditions than today (Bonsall et al., 2002). Certainly over the following millennia, extensive spread of blanket mire (peatland) has been seen in the oceanic climate zone of coastal northwest Europe, and there has been a general southern retraction of northern treelines and downslope movement of upper tree-lines in response to cooler and wetter conditions. These observations suggest that the 5000 ¹⁴C years BP wildwood may not be an attainable target for ecological restoration projects. However, the extent to which these vegetation changes are a pure climate response is debatable. Both human activity and soil processes leading to leaching, gleying, and, from an arboreal plant's perspective, general deterioration of soil conditions in exposed environments as the present interglacial progressed will also have played a part in the changing extent and character of woodland.

Maps showing inferred vegetation for the mid-Holocene (e.g., Bennett, 1989) show something of the great diversity of woodland type that must have prevailed across Europe. However, interpretation of pollen records in terms of vegetation associations and dominance is not simple, and calibration of the pollen record is a key research agenda in contemporary European palynology.

The degree of openness within this wildwood is currently an important and controversial theme for palynologists and landscape managers alike, following Vera's (2000) book, which argued that the wildwood would have had a large proportion of clearings, maintained by large native herbivores. This has led to some reevaluation of the pollen record in terms of openness (e.g., Svenning, 2002), and a lively debate into the interpretation of a range of proxies of past habitat structure is ongoing.

The Elm Decline

When radiocarbon dating was applied to postglacial pollen diagrams, most events (e.g., the arrival of oak and alder in northwest Europe) that had been used by palynologists as biostratigraphic markers were found to be asynchronous. One event stood out; the decline in elm (*Ulmus*), originally identified by Iversen (1941), appeared to be broadly synchronous across northern Europe (Figure 1). A recent review by Parker et al. (2002) shows that statistically the timing of the elm decline varies by about 1000 years across the region, although how much of this is true regional and catchment variation in the event (e.g., real variation in the actual timing of the event), and how much due to the uncertainties of the

dating process (e.g., a synchronous event being 'blurred' by dating error) is hard to establish.

The causes of the elm decline have been extensively debated, and three main possibilities have emerged. These have been reviewed in Pegler and Birks (1993). The first possibility is that the decline is in response to climatic deterioration at the end of the 'Atlantic period' or to soil changes (Parker et al., 2002), although, because elm is apparently the only broad-leaved deciduous forest tree taxon affected, this is not a widely supported hypothesis. A second alternative is direct human agency, partly through the collection of leaf hay for animal feed, which would suppress flowering, and thus, pollen production, and also weaken the tree by creating wounds through which disease could enter. Again, the question of why only elm would be selected for this practice makes this hypothesis less likely. Another possible explanation for a human-caused decline is that elm was preferentially cleared due to particular soil conditions, or that elm was peculiarly vulnerable to competition from other trees in recolonizing areas following human disturbance of woodland during slash and burn type agriculture. The third alternative is that the decline was caused by a severe outbreak of disease affecting elm populations across the region (Pegler and Birks, 1993). This theory is often seen as attractive, especially following the 1980s outbreak of Dutch elm disease in the area. It is supported by a few high-resolution studies of the elm decline at specific sites, for example, at Diss Mere in Norfolk, England, which found a very rapid decline over less than a decade at a time when human activity was not apparent in the record (Pegler and Birks, 1993). The elm bark beetle (*Scolytus scolytus*) is one known vector for the Dutch elm disease-causing agent, a fungus, *Ceratocystis ulmi*. Occasional remains have been recovered from sediments at around the time of the decline (Girling and Greig, 1985). Other apparent pathogen related single-taxon declines occur in other geographical regions, most notably the hemlock (*Tsuga*) decline in eastern North America around 4800 ¹⁴C years BP.

The preferred explanation seems to be that several factors were involved in the elm decline across northern Europe. Human activity was increasing in intensity and changing in type during this mid-Holocene interval, as Neolithic agriculture spread in northern Europe. Woodland management activities such as the collection of leaf hay and increased browsing pressure from domesticated livestock could well have provided increased opportunities for invasion of a disease vector into otherwise healthy trees. Even if human activity were neither the primary cause nor an exacerbating factor in the elm decline, humans are likely to have taken advantage of the opening up of woodland caused by the death of elm trees. It is easier to clear diseased or dead trees than it is to remove living ones, and the natural glades created by the death of trees will have been attractive to grazing animals. Therefore, human activity may have been sufficient to prevent extensive elm regeneration.

Human Activity

The timing and nature of early agricultural activity is a challenge for pollen research. Vegetation disturbance caused by human activity in the landscape before the widespread adoption of agriculture can be detected in pollen records. Especially in the northern and western fringes of Europe, the detection of

Mesolithic period human-mediated modification of landscape is an increasingly active research field (e.g., Whitehouse and Smith, 2004). One way in which people often modify vegetation is by the use of fire. Changes in fire regime can be investigated by analysis of charred particles on pollen slides as well as the investigation of macroscopic charcoal recovered from sediments. Such investigations are an important adjunct to the pollen data and provide more detailed information about landscape change. Whether the first farming in a region occurred as 'slash and burn' style shifting cultivation or the establishment of permanent settlements with gardens, initial openings of the forest canopy will have been small. Detection of small openings in the forest is not easy using pollen signals. Charred particle analyses are often used as evidence of increased fire incidence associated with landscape use by human populations.

Pollen markers for early, that is, Neolithic, agricultural activity include increases in the presence of herbs that have a strong association with human activity, such as ribwort plantain (*Plantago lanceolata*). However, because these taxa also occur naturally in the landscape and do not produce large amounts of pollen compared to trees, their detection is not always easy. Cereal crops are generally poorly represented in pollen records. Among the cereals, only the pollen of rye (*Secale*) can be identified to species. Plant macrofossil evidence indicates that early farmers mostly grew cultivars of wheat (*Triticum*) and barley (*Hordeum*). Comparison of archaeological and paleoecological evidence of cereal agriculture and of human presence often shows that the pollen record evidence 'lags' behind the archaeological evidence.

Evidence of human activity and of agriculture is time transgressive across the European pollen record, and further complicated by the patchy and nonrandom distribution of pollen sites in the landscape. Early agricultural settlement and landscape modifying activity seem to focus largely on areas with light, well-drained soils, which were probably relatively thinly forested and were also most suitable for Neolithic agricultural practices. Archaeological evidence is clustered on areas such as the chalk and limestone Downs and Wolds of southern Britain. This may partly be an artifact of discovery because later peatland and wetland spread may obscure much of the Neolithic landscape in lowland areas. In areas such as the Rhine valley, where deep alluvium deposits have built up during the last few thousand years, the archaeological record of the first farmers is likely to be buried under several meters of sediment. Areas with chalk or sand substrates, apparently attractive to Neolithic agriculturalists, also tend to lack sites suitable for the preservation of pollen records (Brown, 1997).

The main phase of clear human activity-related changes in the landscape recorded in postglacial pollen records from northern Europe is therefore the first broad opening up of the woodland canopy. This likely occurred due to population increase leading to more land being cleared for use or as a result of pastoral activities. The grazing of domesticated livestock is usually managed to varying degrees, generally leading to a concentration of grazers in particular areas such as those within easy reach of the base settlement. Use of land by livestock, including cattle, sheep, goats, and pigs, can substantially suppress the regeneration of woodland tree and shrub species either because the animals deliberately seek out and

preferentially eat seedlings or because seedlings are destroyed as a by-effect of grazing (Davis, 1987). With time, this can lead to greater openness of the woodland canopy as older trees gradually die without replacement, leading to woodland clearance by default rather than by active removal of timber or deliberate clearance. The detection of landscape openness, and its implications for the density of settlement and nature of agricultural practices, is a key driver behind the PollandCal project (<http://www.ecrc.ucl.ac.uk/pollandcal/>).

Another major impact of human activity has been its role in changing the distribution of species (see Crosby, 2003). Examples of this include the introduction into northern Europe of nonnative herbivores (including sheep, goats, and rabbits) and of crop species (such as maize, potatoes, and flax) and associated weeds. The introduction of plants for ornamental and practical purposes has accelerated in the last millennium, as has the translocation of plants beyond their range limits. For example, to the best of our knowledge, larch (*Larix*) and spruce (*Picea*) are not native to the United Kingdom in the present interglacial (Bennett, 1989), yet both are planted widely in the uplands and are recorded in more recent pollen records. In some cases, introductions have had a profound ecological effect on the landscape and on ecosystems. Introduced species may become highly invasive and may displace or outcompete native species; in Britain, *Rhododendron ponticum* (Dehnen-Schmutz and Williamson, 2006) and the gray squirrel (Manchester and Bullock, 2000) are two notable examples that have affected recent vegetation. Other plant species have been moved beyond their apparent natural range limits, for example, with the planting of beech (*Fagus*) and lime (*Tilia*) across northern areas (Bennett, 1989). The macrofossil record is a far more sensitive detector of arriving plant species than the pollen record, but their presence does show up in some pollen diagrams. Relatively recent arrivals and ornamental plantings such as spruce (*Picea*) plantations can actually serve as useful age marker horizons in the pollen record of the last few hundred years.

Current Research Challenges

The postglacial interval in northern Europe is richly represented in pollen records, far more so than any other part of the Quaternary, but this richness of records simply opens up more questions. Reconstructing the postglacial vegetation dynamics of the region is still challenging. Site positioning is not random, and some areas with distinctive geologies, soils, and therefore, presumably ecologies are still 'palynological deserts,' poorly represented or entirely absent from the available database of pollen records. Site size and the dynamics of wetland sedimentary systems are also a challenge for interpretation, because changes in basin size and surface type are known to affect the spatial resolution of the pollen signal preserved. Therefore, one site, undergoing hydrosere succession, records different spatial samples of the surrounding landscape in different seral stages than nearby sites. Comparison between sites of different character must also be adjusted to allow for this effect. Our understanding of the complex relationship between vegetation mosaics and the pollen assemblage forming at a sample point within that mosaic is improving, but there are still many uncertainties in this vital area, particularly around

questions of openness of past forest canopies. Future developments should also progress toward a more integrated paleoecology, drawing on the full range of biotic records available in interpretation and reconstruction.

Intersite comparison and combination of sites for reconstruction of broader patterns of vegetation dynamics also depends on the establishment of reliable chronologies. So far, this has mostly been done by radiocarbon dating, with all the associated uncertainties. The discovery of tephra layers of various ages in some parts of the region holds out the promise of greater confidence in intersite correlation at some specific points in the postglacial. Correlation with the marine record presents a further challenge, which may yield valuable insights into the complex connections between climate and human activity as drivers of postglacial vegetation history in northern Europe.

Summary

Northern Europe has an extensive archive of pollen records of the postglacial interval, but there are still gaps in the spatial coverage. The pollen record reveals the patterns of reinvasion of tree taxa following the last glaciation, as well as the increasing intensity and diversity of human impact on the landscape. However, interpretation of the pollen signal is a developing field, with much still to be done before we can reconstruct past landscapes with confidence and get full value from the large body of data available for the region.

The Current State of Knowledge of Postglacial Pollen Records of Southern Europe

Pollen analysis has proved to be a powerful tool not only to demonstrate changes in plant communities through time but also to investigate changes in past climate and human exploitation of the landscape. The southernmost regions of Europe, together with the Carpathian region, have been found to be important biodiversity reservoirs for the whole continent during glacial intervals. Southern Europe extends south of the 45° parallel. From a biogeographic standpoint, it consists mainly of Mediterranean countries and the islands of the Mediterranean Sea. For the sake of brevity, this article discusses only the most recent papers in which detailed references of previous regional works are provided. A list of sites is provided in [Tables 1–4](#), grouped according to their geographic distribution, and the list of sites used for this synthesis is shown in [Figure 1](#). (In [Figure 1](#) and [Tables 1 to 4](#) a reference to most southern European pollen sites (place, author(s), publication year) is made. A complete list of references can be found in regional syntheses and in recent papers quoted in the text, as it was not possible to include all references.) Dates in this discussion are in calendrical-equivalent (calibrated) years before present (see [Calibration of the ¹⁴C Record](#)). The classical pollen chronozones used for northern and central Europe are deliberately not used in this article because this model does not generally fit the dynamics and timing of changes in the vegetation of southern Europe. Knowledge of the Late Glacial (see [Middle and Late Pleistocene in Southern Europe](#)) vegetation trends is also needed for a better understanding of postglacial vegetation dynamics in southern Europe.

The postglacial reforestation of the various southern European regions shows differences not only in timing but also in vegetation types and dynamics. Many postglacial pollen records of southern Europe show substantial differences between early and late Holocene vegetation development, suggesting a general change from wetter to drier climatic conditions (e.g., [Sadori and Narcisi, 2001](#)). These changes have often been interpreted as reflecting aridification phases leading to the establishment of the present-day Mediterranean climate ([Carrión et al., 2010b](#); [Jalut et al., 2000](#); [Pérez-Obiol et al., 2011](#); [Sadori et al., 2011](#)). However, according to an alternative interpretation, the opening of the forests since the mid-Holocene was primarily linked to human impact, increasing from the early Neolithic onwards ([Kaplan et al., 2009](#)). Palynological research on postglacial environmental changes has, therefore, led to divergent interpretations in terms of natural, as opposed to anthropogenic, factors. One way to shed greater light on the causes of mid-Holocene landscape changes is to use those natural archive records that can be unambiguously attributed to climatic forcing. In many parts of southern Europe, lake level, lake isotope, cave speleothem, and deep-sea sedimentary records (e.g., [Bar-Matthews and Ayalon, 2011](#); [Magny and Miramont Sivan, 2002](#); [Roberts et al., 2011](#)) independently suggest a distinction

between an earlier part of the Holocene characterized by conditions moister than present and favorable to temperate deciduous trees, and a later interval with a drier climate, particularly in summer, favorable to sclerophyllous trees.

Iberian Peninsula and Balearic Islands

Recently, [Carrión et al. \(2010a\)](#) published an updated synthesis of Late Glacial and postglacial records of this region. They succeeded not only in documenting but also in explaining, with selected and meaningful examples, the complex late Quaternary vegetation history of the Iberian Peninsula and Balearic Islands. [Carrión et al. \(2010a\)](#) include a complete list of the currently available regional, terrestrial, and marine pollen records as a supplementary file (see also [Table 1](#)).

At the beginning of the postglacial in Portugal and continental Spain, an increase in moisture and temperature is suggested by the development of deciduous broadleaf forests at low elevations close to the coast and mainly pine (*Pinus*) forest inland and in most mountain regions. Evidence for Mediterranean vegetation with evergreen oaks, probably both kermes oak (*Quercus coccifera*) and holm oak (*Q. ilex*), mixed with steppe and grassland plants, was found in pollen spectra that predate the Holocene in southeastern Spain from the subarid region of Almería. This early reforestation suggests that mesophilous and thermophilous tree refugia were present in southeastern Spain in the late Pleistocene. Evergreen vegetation dominated by the *Quercus ilex* type, with deciduous oak, sparse cork oak (*Q. suber*) and considerable amounts of pine, probably reflecting altitudinal changes of vegetation in the Sierra Nevada mountains, was found in southeastern Spain at Padul during the Late Glacial, since at least 13 ka BP. A similar age for this early reforestation, in which *Quercus* (both evergreen and deciduous) and other angiosperm taxa played an important role, is also found in the lower Guadiana valley, Portugal ([Fletcher et al., 2007](#)). Increases in *Quercus* pollen since the Late Glacial interval show the earliest occurrences in most pollen sites of southernmost and coastal regions of Iberia. After the Late Glacial reforestation, the marked recurrence of glacial conditions typical of northern countries and preceding the postglacial is found in the mountain area of Lago de Sanabria in northeastern Spain. The expansion of deciduous oaks occurred rather late, after 11 ka BP, at Estany de Banyoles in Cataluña.

For the Late Glacial/postglacial transition in Portugal, a relatively humid climate can be deduced from the early paludification of Lagoa do Golfo where deciduous, riparian, and coniferous forests dominated, replacing sclerophyllous maquis shrubland vegetation dominated by evergreen shrubs. Along the coast, at Orla and in the basins of the Tejo and Sado rivers and probably along the whole coastline between Porto and Sines, considerable areas of maritime pine (*Pinus pinaster*) forests were recorded in areas with sandy, unconsolidated soils.

found. The scientific debate about the role of climatic change has been mostly restricted to vegetation dominated by oak and pine. Many sites show high values of pine persisting since the early Holocene, suggesting that mountain pine forests partly covered the inner and Atlantic regions of the Iberian Peninsula. However, during intervals with open woodlands, the effects of over-representation of pine pollen in percentage diagrams should be taken into account. Modern pollen-vegetation relationship studies carried out in northwestern Spain (the Las Pardillas region) provide evidence for the local presence of pine at the beginning of postglacial reforestation (Sánchez Goñi and Hannon, 1999). As suggested by Carrión et al. (2010a), different causes, such as continentality, altitude, and aridity, may have favored pines as opposed to oaks. When analyzing this evidence, the fact that several pine species with quite different ecological features are often not distinguished in the pollen diagrams, has to be taken into account. Thus, the existence of pine woodlands during the Late Glacial and early postglacial can be considered a consequence of the orographic influence in several of the Iberian mountain pollen records. Carrión et al. (2010a), using both palynological and macrofossil data, proposed the following distribution in the Iberian Peninsula: European black pine (*Pinus nigra*) and Scots pine (*P. sylvestris*), representing the inheritance of the glacial pine

woodlands, were probably abundant in the mountains, whereas stone pine (*P. pinea*), occurring since the glacial, was limited to the warmer southern and southwestern regions. Aleppo pine (*P. halepensis*) was widespread in the east and Ebro Valley and favored by the opening of the environment and the onset of

matorral (shrubland and woodland ecoregion of the Mediterranean). Mountain pine (*P. uncinata*) and Scots pine would have formed the timberline in the Eurosiberian thermic (i.e., the boundary between the Mediterranean and Eurosiberian vegetation regions in the northern Iberian Peninsula – see Moreno

et al., 1990), moving to higher elevations during the early Holocene.

However, around 11.5 ka BP, in many mountain Atlantic sites of the Iberian Peninsula (Cantabrian Cordillera and Serra de Estrela), birch (*Betula*) played an important role, preceding and accompanying the expansion of deciduous oaks from around 10.8 ka BP. The reduced amount of steppe vegetation (herbs are mainly represented by grasses) suggests that oceanic conditions were already prevailing in this area by the early Holocene (Carrión et al. 2010a). At the time of the North Atlantic cooling event (ca. 8.2 ka BP, e.g. Rohling and Pälike, 2005), a decrease of pine and an increase of evergreen and deciduous angiosperm trees is recorded from mountain sites in

central and southeastern Spain (Rascafría, Villaverde). A decrease of steppe and an increase of deciduous oaks and thermophilous maquis took place in Almería, indicating the Holocene peak in available moisture. An expansion of fir (*Abies*) and beech (*Fagus*) is recorded in northern Catalonia, while the climate signal is unexpectedly inconsistent either in the Balearic Islands or in the northwestern Iberian regions under Atlantic influence (Muñoz-Sobrino et al., 2004; Yll et al., 1997). In the northwestern Iberian Peninsula, a climate change towards cooler conditions may have brought about a decrease in deciduous oak and an increase in birch. This cooling is radiocarbon dated at around 9.2 cal ka BP, about one millennium before the North Atlantic cooling event.

In southwestern Portugal (Lagoa Travessa), a decrease in pine occurred soon after 7.4 ka BP, and it was replaced mainly by evergreen vegetation after 5.5 ka BP. During the entire mid-Holocene, in some Iberian continental and mountain zones, pine forests seem to have persisted where conifers were not replaced by broadleaf trees as recorded in other areas of southwestern Europe. The substitution of pine with evergreen oak at Navarrés and with deciduous oak at Villaverde occurred at 6.8 ka BP, chronologically matching an apparent change toward wetter (and cooler?) conditions found at Banyoles (decreasing deciduous oak, increasing fir), and at Lago de Ajo (decreasing pine and birch, increasing hazel (*Corylus*)). In contrast, the sudden and sharp decrease in box (*Buxus*) in the mid-Holocene, which led to its local extinction at Minorca in about one millennium, can be interpreted as a sign of increased xeric conditions (Yll et al., 1997) and has been recorded in all the Balearic Islands.

Could the change detected in many peninsular sites be only due to improved edaphic (soil) conditions, which allowed some mesophilous and thermophilous taxa to spread? Although the mid-Holocene was an interval with very low fire incidence and minima in xerophilous taxa, optimal conditions for mesophilous plants were hardly attained in the Mediterranean part of the peninsula until 5.8 ka BP. According to de Beaulieu et al. (2005), the trend toward aridification found in the Balearic Islands also became evident in the peninsula by about 6.5 ka BP. This was due to significant changes in the Mediterranean atmospheric forcing, which progressed from 6.5 to 6 ka BP with the establishment of a drier climate and an increase in seasonality. A different interpretation is advanced and well substantiated for southeastern Spain by Carrión et al. (2010a). In the mountainous areas, in fact, in the period from 7.5 to 5 ka BP, several species of pines, evergreen, deciduous oaks, and other broadleaf trees were widespread. This represented the mesophytic optimum, the xerophytic minimum, and the period of lowest fire activity.

Pérez-Obiol et al. (2011) offer a useful summary of the mid-Holocene climate changes registered in palynological records of southwestern Spain. They propose a rough temporal framing of Holocene climatic changes as follows: a humid phase (12–7 ka BP), a transition phase (7–5.5 ka BP), and an aridification phase (5.5 ka BP–). The timing, extent, and progress of the establishment of the Mediterranean climate had a degree of variability depending on the biogeographic region considered. Close examination of several pollen sequences carried out by Pérez-Obiol et al. (2011) revealed climatic transformations in the flora and vegetation between 7 and 4 ka BP. Three main spatial and taxonomic responses have been identified by them: (1) in littoral regions, deciduous broadleaf trees were frequently dominant and then replaced by sclerophyllous and evergreen forests; (2) in continental regions and sub-Mediterranean mountains, the dominance of pine throughout the whole Holocene signals a change of less magnitude; and (3) in southeastern semiarid Mediterranean regions, the main changes are reflected by alternation between steppe and shrub communities.

The varied responses of the diverse Mediterranean vegetation ecosystems to the gradual mid-Holocene climatic change probably accounts for the time-transgressive nature of changes registered in regional pollen spectra. Many authors, however, attributed these changes to human impact, leading to the

dominance of evergreen sclerophyllous vegetation in the Mediterranean in recent millennia.

Jalut et al. (2000) identified another episode of increased xerophytes and almost complete disappearance of mesophilous trees in the peninsula around 5.1–4.7 ka BP. The 400-year interval is an artifact of imprecise dating. However, the pollen records show sudden change. This climate change is likely to have contributed to the extinction of box in the Balearic Islands.

Recently, Carrión and colleagues (Carrión et al., 2010b) carried out an analysis of the aridification trends and processes that have occurred in the Murcian-Almerian bioprovince, southeast Spain, during the Holocene. The area has experienced a trend toward desertification since at least the Miocene. The human impact is highly variable in this region, and this complicates the distinction between natural and anthropogenic causes. Environmental change was highly variable across southeastern Spain, starting earlier in low-elevation areas and river basins, after 5 ka BP. Forest degradation in the mountains started later (4.3–3.6 ka BP) and reached its maximum during the Roman occupation, around 2 ka BP. The high degree of present-day xerophytization (i.e., plant adaptation to dry conditions) has multiple causes, resulting from a combination of anthropogenic disturbance and resource exhaustion under enhanced aridity.

Pollen records from southern Portugal identify significant vegetation changes between 5 and 3 ka BP, consisting of the expansion of seminatural heathlands and shrublands at the expense of forest vegetation. A wet phase occurred in the mid-Holocene in northwestern and north-central Iberia with increasing hazel, Ericaceae (heath family), and beech, the last being recorded after 4.5 ka BP. Around 3.9 ka BP, the xerophytic component increased in the rest of the peninsula, along with anthropogenic indicators and fires.

Strong evidence of cereal cultivation occurred in some sites soon after 3.2 ka but mainly since Roman times or later, first in lowland sites and then in sites at higher altitudes. The beginning of the extensive cultivation of olive (*Olea*) and grape (*Vitis*) seems to date from the Middle Ages. An arid period preceded and accompanied the Romanization of Iberia (2.7–1.9 ka BP, Jalut et al., 2000), so the effects of human landscape modification must be taken into account from this time onwards.

Southern France, Andorra, and Corsica

The Holocene vegetation history and climate change in Mediterranean France and in the northern slopes of the Pyrenees has been partially summarized in recent papers (Andrieu-Ponel et al., 2000; Jalut et al., 2000, 2009), while the postglacial palynological record of Corsica is discussed in Reille et al. (1997) (see also Tables 2 and 5). Most studies in the coastal regions of Languedoc, Camargue, and Provence (Figure 1) were carried out in flood plains and marshy areas, where pollen was often scarce and poorly preserved, pollen from local vegetation masked the regional pollen rain, and problems with radiocarbon dates often arose (e.g., Andrieu-Ponel et al., 2000). In this regard, a new radiocarbon-dated diagram from Capestang, Languedoc (Jalut et al., 2009), is particularly interesting.

Table 5 Timing and features of the main postglacial vegetational events in southern Europe

Event	Age	Features
<i>Iberian Peninsula and Balearic Islands</i>		
Spread of Postglacial woodlands	Since 10.2 ka BP onward	Spread of deciduous oak forests in coastal and southern mountain sites, of pine and/or birch in most of the northern mountain and continental sites
Start of an aridification phase	7.5–7 ka BP	A slow and prolonged climate forcing does probably account for its time-transgressive character
Climate change toward cooler and/or wetter conditions?	Since 6 ka BP	Found mainly at mountain sites, it could also be due to improved edaphic conditions which allowed the spread of more demanding water taxa
Strong climate change with increase in aridity and seasonality	6–4.5 ka BP	First detected in Balearic Islands (reduction and extinction of <i>Buxus</i> at Minorca), then in the rest of the Mediterranean part of the peninsula
Human presence	3.5–3 ka BP	Forest opening through cutting, burning, and grazing (possible synergy of human and climate forcing) and begin of cultivation
Arid phase	2.6–1.9 ka BP	Detected through pollen ratios, it preluded and accompanied the impact of the Romans
Human impact	2 ka BP onward	Strong forest clearance and extensive land exploitation. Cultivation of <i>Juglans</i> since ca. 2 ka BP
<i>Southern France and Corsica</i>		
Spread of Postglacial woodlands	Since around 1 ka BP	Conifer trees on the Pyrenees mountains, thermophilous forests at middle and low elevations
Arid phase	7.500–7 ka BP	Detected through pollen ratios
Increase of aridity	6 ka BP	Expansion of Mediterranean taxa. It was interpreted as the effect of human impact, but at least a synergy of climate and humans should be taken into account
Climate change with increase in aridity and seasonality and human presence	4.500–4 ka BP	Human populations probably just strengthened a climate forcing which led to a well-developed Mediterranean vegetation. Evidence of grazing from the Pyrenees
Human impact	Since around 2.6 ka BP	Cultivation both in plain and in mountain regions. Cultivation of <i>Juglans</i> since ca. 2.2 ka BP
<i>Peninsular Italy and Sicily</i>		
Spread of Postglacial woodlands	Since around 10.500 ka BP	Spread of thermophilous forests (deciduous <i>Quercus</i> dominant) in central and southern Italy and with <i>Abies</i> in northern Italy
Beginning of a climate trend toward aridity	(8) 7.5 ka BP	Beginning of <i>Q. ilex</i> continuous curve in central Italy (8 ka BP) and increase (7.2 ka BP) of <i>Olea</i> in Sicily
Arid climate change	ca. 3.7. ka BP	Forest clearance without fires and changes in wood composition, detected in Latium. Does it correspond to the northern Italy decrease of <i>Abies</i> (and partly <i>Quercus</i>) of 3.8 ka BP?
Human presence	3.6–3.5 ka BP	Human forest clearance, cultivation of cereals, legumes, olive (probable in Sicily), presence of secondary anthropic indicators and use of fire
Human impact	Since around 2.7 ka BP	Extensive cultivations, strong land exploitation. since around 2.7 ka BP <i>Juglans</i> in Sicily, <i>Castanea</i> widespread near Rome. Disappearance of <i>Abies</i> at Monticchio?
<i>Southern Balkan Peninsula, Dalmatian Islands, and Crete</i>		
Spread of Postglacial woodlands	Since around 10.600 ka BP	Spread of thermophilous forests (deciduous <i>Quercus</i> dominant) and conifer woods at some mountain sites
Arid phase at low-elevation sites?	9–8 ka BP	Maxima of <i>Pistacia</i> pollen interpreted as an indication of open environments
Climate trend toward wetness	7.5–6 ka BP	Reduction of deciduous <i>Quercus</i> and increase of one or more of the following taxa: <i>Corylus</i> , <i>Carpinus orientalis/Ostrya</i> , <i>Ulmus</i> , <i>Tilia</i> , <i>Abies</i> , and <i>Pinus</i> in upland sites of northern Greece and western Bulgaria
Arid climate event	7.2 ka BP	Reduction of deciduous <i>Quercus</i> , increase of <i>Pistacia</i> and <i>Juniperus</i> detected in Mljet Island
Human presence	5–4.5 ka BP	Probable man-induced forest clearance, increasing pasture, and secondary anthropic indicators
Human impact	Since around 4–3.5 ka BP	Probable extensive cultivations of <i>Olea</i> since the Bronze Age; <i>Juglans</i> (with <i>Ceratonia</i> in Crete) since around 3.3 ka BP

In the mountains of Corsica, Late Glacial pollen assemblages included alder (*Alnus*), birch, deciduous oak, juniper (*Juniperus*), and low amounts of pine pollen (<20%). Such a low percentage of pine pollen suggests its absence in the island from 13.9 to 11.9 ka BP, but pine dominated forests developed in the following centuries (Reille et al., 1997). At high elevations in Corsica, two

types of mesophilous forests were dominant from 8.9 to 2.7 ka BP: deciduous oak forest and mixed forest with yew (*Taxus*). At lower elevations, tree heath (*Erica arborea*) spread, while *Quercus ilex* type did not play a significant role until 5.1 ka BP.

At the onset of the Late Glacial reforestation, open landscapes with conifer trees and shrubs were common both in the

Pyrenees and on the plains of southern France. The Pyrenees acted as a Late Glacial refugium for mesophilous and thermophilous trees. Since ca. 12 ka BP, temperate forests, including mainly deciduous oaks with birch, hazel, and hornbeam, dominated the low and medium elevations in southern France and also along the Mediterranean coast. After 9.5 ka BP, fir pollen increased in plains records (Biot, Rhone valley, and Palavas), reflecting its expansion in the southern French Alps, in the northern Rhone valley, and in the southern Massif Central. Until recently, the slight increases of *Quercus ilex* and other sclerophyllous taxa from ca. 8 to 7 ka BP were interpreted as exclusively anthropogenic. It was thought that Neolithic populations heavily utilized this tree. Actually, beech and fir also increased during this interval together with Mediterranean taxa, thus leading to a different climatic reconstruction.

The new palynological record (Jalut et al., 2009) from the former pond of Capeatang (Languedoc) spans the entire Holocene, providing information for the last 12 000 years. After a phase dominated by pine, a deciduous forest is established about 10.2 ka BP. Hazel is more abundant than deciduous oak until 8.5 ka BP. Beech shows an expansion together with *Quercus ilex* type from 4.5 to 3 ka BP. The contemporary presence of such different vegetation types, a beech forest and a Mediterranean forest, can be explained by their differing altitudinal distributions, as the latter type of vegetation is the more thermophilous. Around 3–2.8 ka BP, *Fagus* and deciduous *Quercus* decrease and the forest becomes more open, with increased *Pinus*, grasses, and evergreen thermophilous or Mediterranean taxa.

Jalut et al. (2000) characterized climate changes along the Mediterranean coast of Spain and southwestern France, identifying an arid phase from 8.3 to 7.8 ka BP, followed by four other similar changes, the last of which was recorded in the Middle Ages. Human impact probably strengthened the impact of climate forcing, leading to well-developed Mediterranean vegetation during the late Holocene. Could migration delay and establishment time (e.g., edaphic requirements) have influenced the timing and selection of tree establishment? If so, then climatic forcing could be ruled out as the cause of the spread of beech and fir. On the basis of malacofauna (mollusk) analyses, de Beaulieu et al. (2005) concluded that during the Holocene, the Mediterranean ecosystems were patchy and frequently open. Such a structure may partly explain the ability of mountain taxa such as fir and beech to colonize some empty niches in the Mediterranean hills during their major expansion phases. In addition, long distance transport of exotic pollen cannot be excluded.

The recent study of the Planells de Perafità fen (Andorra) led Miras et al. (2010) to hypothesize a quite early human impact, dating back at ca. 8.4–8.1 ka BP. Because of uncertainties in grass pollen identification, the claimed cultivation of cereals in ca. 5.1 ka BP in Languedoc is not certain. Around 5.1–4.5 ka BP, at medium and high altitudes in the Pyrenees, pasture maintenance was a common practice (Jalut et al., 2000). Clear signs of human landscape modification are found in the Pyrenees since ca. 2.7 ka BP and in the plain close to Montpellier (Capeatang) since ca. 2.6 ka BP. A similar date marks the start of presumed forest clearance in the vegetation of Corsica. There, Jalut et al. (2000) detected an arid period, beginning around 2.7 ka BP. As in Spain, so also in France, sparse walnut (*Juglans*) pollen grains are found in

pollen spectra from ca. 7.8 ka BP, while the cultivation of this tree began around 2.2 ka BP. The exploitation of olive and chestnut (*Castanea*) in southern France dates back to the Middle Ages.

Peninsular Italy and Sicily

From the sector of northern Italy south of 45°, information on past vegetation comes from a few Alpine and some north Apennine mountain lakes. Most Holocene pollen records of central and southern Italy originate from extant or drained crater lakes, while the only insular record spanning the whole postglacial is from the center of Sicily (see Tables 3 and 5). An overview of the palynological research in Italy, including both Pleistocene and Holocene records, was recently published by Magri (2007) and is recommended for a complete reference list.

Throughout Italy, Late Glacial pollen spectra are characterized by significant levels of mesophilous tree pollen, especially deciduous oaks, birch, hazel, linden (*Tilia*), and elm (*Ulmus*). The only exceptions are the southernmost alpine lacustrine records (Laghi dell'Orgials and Lago delle Fate, Maritime Alps). The pollen diagrams from the Maritime Alps show the typical features of central European countries and the classical pollen chronozones, with pines dominant both in the Late Glacial and in the postglacial and broadleaf trees almost absent. In central Sicily and in most central Italian sites, sporadic evidence of thermophilous trees and shrubs occurs after the end of the glacial. Refugia areas for most trees were not far from the investigated sites. The expansion of forests was temporarily interrupted during the Younger Dryas interval but actually started at most sites by 12.5 ka BP. Closed forest conditions developed at different times in central and southern Italy ranging from 11.9 ka BP in the north to 10.2 ka BP in the south. At Gorgo Basso (Tinner et al., 2009), a coastal lake of Sicily, true forest conditions were never reached, but a *Pistacia* shrubland became established around 10 ka BP.

Postglacial pollen spectra are characterized by high, though fluctuating, percentages of deciduous oaks from the mountain areas of Sicily (together with evergreen oaks at Lago di Pergusa) to northern Italy (northern Apennines). Deciduous oak forests are generally dominant in the plains and hilly sites of central Italy. Throughout the postglacial in Latium (e.g., Lagaccione, Lago di Vico, Valle di Castiglione, Lago Albano, Lago Lungo), they are accompanied by beech (*Fagus*) during the first part of the postglacial. Other main taxa in the first half of the postglacial are described in the following paragraphs.

Fir (*Abies*) was very important in the western sector of the peninsula and was found from the early postglacial in the northern Apennines (Lowe and Watson, 1994). It played an important role, with expansion in areas close to the sea from 9.8 to 7 ka BP (Bellini et al., 2009) in eastern Liguria and northern Tuscany. It was recorded from the beginning of the pollen diagram (7 ka BP) to 6 ka BP at Massaciuccoli, but it probably occurred earlier as suggested from the more southern site of Lago dell'Accesa, where it was found in the interval 10.2–6 ka BP. Fir pollen occurs sporadically in northern Latium Holocene records, suggesting a long distance transport.

Hazel pollen has been found from the early postglacial, followed by *Quercus ilex* type with beech, after ca. 9.8 ka BP in northern Latium. Hazel and fir pollen have been found (the

latter since around 6.8 ka BP) in postglacial spectra from Basilicata (Lago Grande di Monticchio). *Quercus ilex* type pollen with olive pollen (the latter increasing since around 8 ka BP) has been found in Sicily. In Sicily, oak forests persisted, even if progressively decreasing, from about 8.3–8.1 ka BP to about 4.2 ka BP. In Latium, mixed deciduous oak woods were widespread from 10 to 4.1 ka BP. Favorable climatic conditions for fir and deciduous oak forests persisted in the northern Apennines until ca. 4.2 ka BP, when beech woods increased. Fires were almost absent regionally from ca. 8.3 to 4.5 ka BP, but fires of anthropogenic origin began around 4 ka BP. Human disturbance also coincided with increased aridity in Sicily as early as ca. 8.9 ka BP. At about the same time, the expansion of Mediterranean vegetation in central Italy began. It is surprising that at ca. 6.8 ka BP, upland sites of the northern Apennines registered the first appearance of sparse grains of olive and a late expansion of beech, possibly for edaphic or topographic reasons.

In the last few years, research has been concentrated mainly in coastal areas such as lagoons, marshy zones, coastal plains, and ancient harbor areas. The studied records depict a mosaic of different vegetation types for the last 10 ka with a high regional variability. From 9 to 6 ka BP, the records from the Ligurian and Tyrrhenian coast are characterized by high percentages of fir, probably growing close to the sea. At the time, Mediterranean vegetation, characterized by *Pistacia* and then by *Olea*, was already established in Sicily at both Gorgo Basso and Biviere di Gela (Tinner et al., 2009). The development of open mesothermophilous woods and Mediterranean maquis in the coastal plains of southern Liguria and Tuscany dates back to 7 ka BP after the local disappearance of fir. More to the south, just north of the Tiber delta, at Stagno di Maccarese, a quite similar situation is found, with riparian fresh water trees playing an important role (Di Rita et al., 2010). From the Adriatic side of the peninsula in Apulia, the available data come from Lago Alimini Piccolo (Di Rita and Magri, 2009) and the former Lago Battaglia, with evergreen Mediterranean vegetation dominant from the beginning of the records at ca. 5.5 ka BP and at ca. 6 ka BP, respectively. The last couple of millennia are well represented in harbor basins, of riverine (Pisa port, Mariotti-Lippi et al., 2006), deltaic (Rome port, Sadori et al., 2010) and marine (Naples port, Allevato et al., 2010; and Lago d'Averno, Gröger and Thulin, 1998) origin.

Recently, Sadori et al. (2011) carried out a comparison of selected pollen records from the central and eastern Mediterranean to detect climate changes in the mid-Holocene. The role of changing seasonality appears to be crucial for this region (Magny et al., 2012). Precipitation seasonality increased during the early to mid-Holocene, with winter precipitation attaining a maximum and summer precipitation, a minimum. At least three rapid climate events with changes in plant biomass are recorded: an abrupt and short change around 8.2 ka BP, one centered around 6 ka BP, and one soon after 3 ka BP. From the beginning of the Bronze Age (ca. 4.4 ka BP in this region), human impact overlapped with a climate change, probably bipartite, toward dryness.

In fact, anthropogenic pollen types have been found in many sites of central and southern Italy since about 3.9–3.8 ka BP. Forest opening occurred in Latium at about 4.2–4.1 ka BP,

associated with aridity. This sudden decrease in regional arboreal pollen concentration followed a previous decline at ca. 4.9–4.7 ka BP. This twofold climate change was followed rapidly by strong human impact. Since Roman times, humans were affecting the vegetation throughout Italy. This probably overlapped with climate change, and the two factors cannot be disentangled.

Southern Balkan Peninsula, Dalmatian Islands and Crete

Since the review by Willis (1994), many new data from the region have become available (see Tables 4 and 5). Among these, several studies from the western mountains of Bulgaria, shedding new light on glacial refugia, are available (Tonkov, 2003; Tonkov et al., 2008). New pollen records have been published from Crete (Bottema and Sarpaki, 2003 and references therein) and from the Dalmatian islands of Mljet and Cres and from western Greece (Jahns, 2005). A particular increase in information about eastern Mediterranean palynology comes from Albania, where big lacustrine basins are present. Two of them are wide and transboundary lakes, namely Lake Ohrid and Lake Shkodra. There are current (Lake Shkodra; Zanchetta et al., 2012) and already well documented (ancient Lake Maliq, Denéfle et al., 2000; and Lake Ohrid, Wagner et al., 2009) research about them and the postglacial vegetation and climate history of the region. A review article (Sadori et al., 2011) presented new pollen curves from Mljet, Voulkaria and Maliq.

Regionally, coniferous trees, with patches of mesophilous and thermophilous taxa, characterized the Late Glacial interstadial. The early expansion of oak woodland (ca. 13.9 ka BP) at Kopais, Greece, mirrors a similar spread in southeastern Spain and central Italy. Due to sampling problems at the Lake Ohrid (284 m max depth), the 40 ka core investigated by Wagner et al. (2009), taken at the considerable water depth of 105 m, shows a hiatus during the Late Glacial. Last glacial vegetation included deciduous oaks, which accompanied the pine spread of the first half of the Holocene. Postglacial forest expansion was, in fact, mainly by deciduous oak and accompanying taxa, but it varied widely across the Balkan Peninsula, suggesting different possible locations of single taxa refugia. The spread of forest was not synchronous. A dense canopy forest was established in northwestern Greece by 12.5 ka BP, while in northern Greece and in southern Bulgaria, woodlands remained fairly open until ca. 10.2 ka BP. Around 11.9 ka BP, an intermediate forest cover was established on the island of Cres (Croatia). In the northern Pirin Mountains of Bulgaria, deciduous woods with pines and birch upslope began to spread at this time. Along the southeastern Black Sea coast (Filipova-Marinova et al., 2004), there is evidence for early postglacial migration of deciduous trees (oak, elm, linden, European ash (*Fraxinus excelsior*) and maple (*Acer*)) from their Late Glacial refugia in the Strandzha Mountains of southeast Bulgaria.

In the mountains of northwest Greece, dense forests were established by 11.9 ka BP or a few centuries thereafter. A slight but noteworthy expansion of *Pistacia* (probably *P. terebinthus* in most sites) occurred during the early Holocene throughout much of Greece (Lawson et al., 2004). Its peak between 10.2

and 8.9–8.3 ka BP suggests an aridity phase. This spread was also recorded in Crete, with maximum values at 8.9 ka BP. Here, open deciduous and evergreen oak woodland dominated. There is no evidence of this dry phase in either Bulgaria or in the northern Adriatic island of Cres. In western Greece, at Lake Voulkaria (Jahns, 2005), pollen of pistachio (*Pistacia*) is present since the beginning of the Holocene. A change was found in most upland sites from Greece, Bulgaria, and Albania (Denèfle et al., 2000) between 8.3 and 6.8 ka BP. This was marked by decreasing levels of deciduous oak pollen and by increasing levels of one or more of the following taxa: hazel, hornbeam or ironwood (*Carpinus orientalis/Ostrya*), elm, linden, beech, fir, and pine. As strikingly similar vegetation dynamics were found during previous interglacials, many possible explanations have been advanced, but the pattern rules out anthropogenic intervention (see Pollen Records, Last Interglacial of Europe). Among the explanations, a shift toward wetter/cooler conditions and the development of soils with humic horizons (Tonkov, 2003 and references therein) seem probable. On the other hand, the expansion of hornbeam (*Carpinus betulus/Ostrya*) and beech found at Lake Maliq may point to conditions of lower availability of moisture and warmer winters because these tree taxa are tolerant of dryness but intolerant of winter cold (Denèfle et al., 2000).

An important change was found in a quite different landscape at the Adriatic island of Mljet around 8.1 ka BP. Here, a partial replacement of deciduous oak by juniper and *Phillyrea* resembles the start of the slow spread of many sclerophyllous trees found in Sicily and in central Italy. This change is synchronous with the aridity phase in the southwestern Mediterranean from 8.3 to 7.8 ka BP.

Unequivocal human intervention in the Balkans is detected only very late in the pollen record. The first sign of anthropogenic disturbance consists in a reduction of both forest density (increasing pasture and secondary anthropogenic indicators) and/or diversity (reduction of deciduous oaks and appearance or increase of fruit trees and/or Ericaceae). Such signals are found in most pollen diagrams only after 5.7–5.1 ka BP. It is worthwhile to note again that a ‘Mediterraneanization’ of the climate could likewise have produced such a vegetation change. Fruit tree pollen appeared very early, although in low amounts. Most of these trees were present in the region since early Holocene. In some sites, walnut pollen grains appeared or increased at ca. 3.5 ka BP (together with *Ceratonia* in Crete). Some centuries later, the pollen of these cultivars was spread throughout Greece and Dalmatia. The onset of olive cultivation is difficult to define because it is not clear if the expansion found at least since the Bronze Age (as in Sicily) could be ascribed to a natural spread of this native plant. From Greek times (i.e., late Bronze Age) onwards, human impact produced strong landscape changes culminating in the present conditions.

Conclusions

The postglacial vegetation history of southern Europe is characterized by dynamic processes in which no additional plant taxa entered the region. All the pollen taxa found in the region have been here since the end of the last glacial. It is clear that a

complex pattern of climatic change prevailed across the region throughout the postglacial interval (Table 5).

Some common trends appeared in southern Europe (Spain, France, Italy, and western Balkans), in addition to a number of rapid climate events with changes in plant biomass (Pérez-Obiol et al., 2011; Sadori et al., 2011). Moreover, strong regional differences in vegetation history occurred, likely linked to regional differences in the climate and to problems in chronological assessments of individual records. Pollen data can in fact be the product of either climate changes or human activity or both. The dilemma can be resolved using a multiproxy approach, comparing pollen data to information about lake level changes and data from lake and cave isotopes, the records of which are less ambiguous with respect to an anthropogenic signal. In addition, when synthesized, primary paleoclimate data from isotope records and speleothems are compared with regional-scale climate modeling simulations, both model output and proxy data suggest an east-west division in Mediterranean climate history (Roberts et al., 2011).

The onset of reforestation began around 12.4 ka BP, with different vegetation dynamics and woodland densities in the various regions. In recent years, it has become clear that establishing the timing of these events requires improved chronologies for regional pollen records. The so-called climate optimum for deciduous oaks (the dominant taxon of the early Holocene) began around 10.2 ka BP, but its duration and areal extent varied from region to region. The 8.2 ka BP abrupt event identified in North Atlantic cores has only been detected in some Mediterranean sites. Many southern European records show substantial differences between early and late Holocene vegetation. They suggest a general evolution from wetter to drier climatic conditions with clearly arid phases (see Paleoclimate Relevance to Global Warming) in southwestern Europe, leading to the establishment of the modern Mediterranean climate. This trend began around 8.3 ka BP, marked by slight increases in pollen from sclerophyllous taxa and culminating around 5.1–4.5 ka BP. In contrast, southeastern Europe apparently experienced increased humidity from ca. 8.3 to 5.7 ka BP. Around 5.7–5.1 ka BP, marked changes in woodland range, density, and composition occurred, and typical Mediterranean vegetation spread throughout the Mediterranean basin. However, anthropogenic effects cannot be ruled out even if there is no doubt that humans alone could not have caused major synchronous changes in vegetation throughout the Mediterranean region. In recent millennia, humans modified the vegetation through livestock grazing, cultivation, burning, and associated living activities. Such activities either caused or exacerbated the decline in forest cover, disguising the climate signal. Human impact on the southern Mediterranean landscapes is hard to detect in pollen diagrams before the Bronze Age (Sadori et al., 2011), probably because prior to this, human impacts were predominantly local in scale and did not affect regional vegetation patterns to any great extent. The best way to study these phenomena is by combining continuous records of proxy vegetation and climate change such as lake cores located as close as possible to archaeological sites, which are the direct link to the region’s cultural history. Throughout the postglacial, human populations modified the plant landscape more or less strongly, but the climatic changes were the determining factors on the development of southern European environments.

Human populations were obliged to adapt to natural environmental variations, increasing their impact and the environmental consequences of global changes.

Introduction

Stratigraphy, derived from the Latin 'stratum' and the Greek 'graphia,' was traditionally considered to be the science of rock strata. However, the definition has now been broadened to include nonlayered sedimentary rocks (e.g., diamictite), igneous rocks, and metamorphic rocks. Indeed, the general scope of stratigraphy includes all rocks forming the crust of the Earth (and other planets), whether consolidated or unconsolidated, and their organization into distinctive stratigraphic units based on their properties and attributes. Stratigraphic procedures include the description, classification, naming, and correlation of stratigraphic units for the purposes of establishing their relationships in space and time. Thus, stratigraphy is concerned not only with the stratigraphic order and age relationships of rock bodies, but also with their distribution, lithology, fossil content, and all other properties and attributes. Stratigraphy also includes the interpretation of environment and mode of origin of rocks and their geological history (Jackson, 1997; Salvador, 1994).

The use of the term 'rock' to describe Quaternary strata that are unconsolidated or semiconsolidated may seem inappropriate

at first sight. However, such usage is consistent with that adopted by the International Stratigraphic Guide (Salvador, 1994), and therefore, the term 'rock' is used here in its broadest sense.

Stratigraphic classification, which underpins almost all Quaternary research, is the arbitrary but systematic organization of rocks into units based on any of their attributes and properties. The three most common formal units of stratigraphic classification are lithostratigraphic (based on lithological properties), biostratigraphic (based on fossil content) and chronostratigraphic (based on time of formation), but other kinds of stratigraphic units are also defined, including magnetostratigraphic, sequence stratigraphic, climatostratigraphic, and so on. While each kind of stratigraphic unit may be useful in stratigraphic classification in certain areas, or for particular purposes, chronostratigraphic units are recognized worldwide and offer the best means of international communication among stratigraphers. Formally defined global chronostratigraphic units comprise the international Geological Time Scale (GTS), and include such major units as the Holocene, Pleistocene, Pliocene, and Miocene Series, which together constitute the Quaternary and Neogene Systems.

It is essential that named stratigraphic units have their characteristics and boundaries clearly described so that they may be recognized away from the place (type locality or type section) where they were originally defined and named. The nomination of a type locality or section also allows other people the opportunity to visit and study the site and to ensure that everyone has the same understanding of the character and definition of the unit.

Comprehensive rules for defining stratigraphic units are given in the International Stratigraphic Guide (Salvador, 1994).

Stratigraphic Correlation: Principles and Methods

Stratigraphic correlation is the process by which stratigraphic units in different places are shown to be similar in character and/or stratigraphic position. Correlation may be on the basis of lithology, fossil content, age, or any other property (Jackson, 1997).

Some Basic Principles

A fundamental principle in stratigraphic correlation is the Law of Superposition, first articulated by Nicholas Steno in the seventeenth century, which states that in any stratigraphic sequence that is not overturned, the youngest stratum is at the top and the oldest is at the base. The Law of Superposition is important in establishing the relative age of units in a stratigraphic sequence, and also for local, regional, and global correlation. For example, the correlation of oxygen isotope stages between two or more deep-sea cores can usually be achieved by matching the pattern of isotope variations from the sea floor downward provided that the sediment cores lack unconformities and that no significant sediment is missing at the core top.

Another fundamental principle is that older landforms and associated deposits are commonly found higher in the landscape than younger ones. This is due to the general tendency of erosional processes to lower the landscape, often assisted by tectonic uplift. Thus, a flight of river terraces will increase in age with elevation, as a consequence of progressive fluvial down-cutting. Up until the early 1970s, marine terraces were often correlated from region to region on the basis of elevation. However, with the recognition of the significant role of tectonism and the advent of modern dating methods, especially U/Th dating of corals, the shortcomings of altimetric correlation became apparent.

Commonly Used Methods of Correlation

1. *Lithostratigraphy*: Lithostratigraphy is the basis for most geological mapping and for description of stratigraphic sections, both in outcrop and in drill holes.
2. *Biostratigraphy*: Whether it be microfossils in deep-sea sediments or the distinctive floras and faunas (including human culture) of continental deposits, biostratigraphy is one of the principal methods of correlation. Some of the best known large mammal fossils of the Quaternary, such as woolly mammoths (Figure 1), are most important for continental biostratigraphy.

Figure 1 The author, holding a late Pleistocene woolly mammoth tusk, recovered by gold miners in Bonanza Creek, near Dawson City in the Yukon, northwest Canada. Such vertebrate fossils are well preserved in the permafrost zones of the Northern Hemisphere.

3. *Tephrostratigraphy*: Tephrae represent almost instantaneous events and enable very precise correlation both within and between marine and terrestrial sequences. Once a tephra is dated at one site, the age can be 'transferred' to all other sites where the tephra occurs.
4. *Magnetostratigraphy*: The major magnetic reversals provide important chronostratigraphic markers in the Quaternary, including those associated with the proposed Lower/middle Pleistocene boundary (Matuyama/Brunhes reversal), the Plio/Pleistocene boundary (top of Olduvai Subchron), and the base of the Gelasian Stage (Gauss/Matuyama reversal). Magnetostratigraphy also plays an important role in marine-terrestrial correlation.
5. *Geochronology*: Geological dating methods yield numerical age estimates that are being increasingly used for correlation. However, all age estimates have field and laboratory uncertainties that must be assessed.
6. *Climatostratigraphy*: Since the recognition of widespread glacial deposits of Quaternary age in the early nineteenth century, global climatic changes, driven by astronomical variations, have provided a climatostratigraphic framework for correlation.
7. *Sea level*: Sea level is recognized as a potential global reference for correlation of shoreline deposits. However, tectonic and isostatic factors, a lack of precise numerical

ages, and problems in identification of paleo-sea-level datums have hindered its use. The Last Interglacial shore-line (~120–130 ka), with the paleo-sea-level a few meters higher than at present, is one of the most widespread datums for measuring tectonic deformation.

8. *Aminostratigraphy*: Fossil proteins contain amino acids that undergo racemization depending on elapsed time, the nature of the fossil material, and a range of environmental factors, including temperature. The extent of racemization is used for correlation.
9. *Oxygen isotope stratigraphy*: Oxygen isotope variations in Foraminifera from deep-sea cores have become the global reference for Quaternary stratigraphic correlation. Astronomical tuning provides a precise chronology.
10. *Sequence stratigraphy*: Originally developed by the oil exploration industry for interpreting seismic section, sequence stratigraphy works best in continental shelf sediments where facies architecture is controlled by relative sea-level changes. In Wanganui Basin, New Zealand, sequence stratigraphic models can be tested against the known history of Quaternary sea-level changes.
11. *Pedostratigraphy*: Paleosols are used for correlation, particularly in loess sequences, and they have also been used for paleoclimate reconstructions.
12. *Morphostratigraphy*: Glacial moraines and outwash terraces are often correlated using morphostratigraphy.
13. *Magnetic susceptibility*: Magnetic susceptibility variations in Chinese loess sequences show a pattern very similar to that of oxygen isotope records in deep-sea cores, and allow

correlation on a cycle-by-cycle basis between the two records, supplemented by magnetostratigraphy.

14. *Chemostratigraphy*: Chemostratigraphy is particularly valuable in ice cores and deep-sea cores. For example, the sulfate concentration in ice cores is used to identify volcanic eruptions.
15. *Geophysical measurements*: Geophysical measurements are used for correlation in deep-sea cores and in downhole logging of boreholes.

A Global Stratotype Section and Point for the Pleistocene

After a century of uncertainty, the 18th International Geological Congress (London, 1948) resolved to select a stratotype for the Pliocene–Pleistocene boundary and to ‘place the boundary at the horizon of the first indication of climatic deterioration in the Italian Neogene succession’ (King and Oakley, 1949). After consideration of the suitability of several sections over the next three decades (see discussion in Aguirre and Pasini, 1985), the Vrica section 4 km south of Crotona in Calabria, southern Italy (Figure 2, inset), was finally selected as the Global Stratotype Section and Point (GSSP), culminating in the ratification of the Plio–Pleistocene boundary, at the base of the marine claystones conformably overlying bed *e* in the Vrica section (Aguirre and Pasini, 1985). Subsequently, the GSSP for the Pleistocene (and Quaternary) was changed to the base of the Gelasian Stage, defined in the Monte San Nicola section in Sicily (Gibbard et al., 2010; Rio et al., 1998),

Figure 2 Correlation of Vrica GSSP to Wanganui Basin, New Zealand. Reproduced from Naish TR, Abbott ST, Alloway BV, et al. (1998) Astronomical calibration of a Southern Hemisphere Plio–Pleistocene reference section, Wanganui Basin, New Zealand. *Quaternary Science Reviews* 17: 695–710. Inset shows Vrica section with sapropel layers labeled.

with the Vrica GSSP to be used to define the base of the Calabrian Stage.

A primary requirement of any GSSP is that it provides multiple criteria for correlation of the boundary. In the case of the Vrica and Monte San Nicola GSSPs, the main methods of correlation are magnetostratigraphy and several marine microfossil datums, including Foraminifera, coccoliths, and ostracods (Aguirre and Pasini, 1985; Rio et al., 1998). In addition, regional lithostratigraphic correlation of sapropels has enabled the sections to be astronomically tuned, yielding an age of 1.806 Ma for the Vrica GSSP and 2.588 Ma for the Monte San Nicola GSSP (Lourens et al., 1996).

Prior to detailed study of the Italian sections, the principal means of correlation was climatostratigraphy. Thus, the base of the Pleistocene Series was equated with a putative major global cooling event that was variously identified on the basis of glacial till, pollen analysis, and faunal evidence. In New Zealand, for example, the incoming of the Sub-Antarctic scallop, *Zygochlamys delicatula*, to Wanganui Basin was estimated to represent the base of the Pleistocene, at a stratigraphic level that we now recognize to be at about 2.5 Ma, just above the Gauss/Matuyama boundary. At the time, it was widely accepted that the Pleistocene was characterized by just four major glaciations (named Gunz, Mindel, Riss, and Wurm in the European Alps), but later, when it became apparent that there were many more glacial episodes, the difficulties of using only climatostratigraphy became readily apparent.

The first precise correlation of the Vrica GSSP to New Zealand was achieved by Beu and Edwards (1984), and refined by Naish et al. (1998), using a combination of biostratigraphy, magnetostratigraphy, and cyclostratigraphy (Figure 2). It is noteworthy that this correlation can be achieved without numerical ages – it is not necessary to know the precise age of a chronostratigraphic boundary to successfully correlate it to other areas.

Stratigraphy by Numbers?

Modern dating methods provide numerical age estimates for a spectacular range of geological materials. Indeed, there are many situations in which age is the only means of correlation. However, correlation on the basis of age is dependent on a full evaluation of dating uncertainties and limitations, some examples of which are given in the following section.

Radiocarbon Dating at the Limit

The type locality of the Salmon Springs Glaciation near Sumner in Washington, northwestern USA, contains two units of interbedded gravel and till (drift), separated by 1.5 m of nonglacial sediments that include tephra, silt, and peat. The peat was dated at $71\,500 \pm 1700$ –1400 years BP (Stuiver et al., 1978), and both drift units were considered to represent a glacial episode during the early to the middle part of the last (Wisconsin) glaciation. The Salmon Springs Drift was widely correlated throughout the northwest United States, largely on the basis of ordinal sequence (glacial deposits that preceded

the last advance of the Cordilleran ice sheet were generally correlated with the Salmon Springs).

However, the age of the Salmon Springs Glaciation was considerably revised when Easterbrook et al. (1981) reported a zircon fission track age of 0.84 ± 0.21 Ma for the tephra at the type locality. Furthermore, the immediately overlying silts were of reversed polarity magnetization, consistent with an age of >0.78 Ma (i.e., older than the Mauyama/Brunhes polarity reversal). Presumably, the ~ 70 ka radiocarbon age was grossly in error as a result of minor, but significant, contamination by modern carbon. It is noteworthy that the validity of the Salmon Springs Drift as a stratigraphic unit is not compromised by the dramatic change in age because it is defined at its type locality, which remains unchanged. Indeed, the identification of a tephra at the type locality enhances the correlation potential of the Salmon Springs Drift with other sites.

A strikingly similar dating situation was encountered in the glacial deposits of Tasmania, where *Phyllocladus* wood in varved clays associated with the Linda Moraine gave a radiocarbon age of $26\,480 \pm 800$ years BP (Gill, 1956). This age was for a long time accepted as dating the Last Glacial Maximum in Tasmania. Subsequently, redating of the site yielded a radiocarbon age of $>40\,000$ years BP (Colhoun, 1985), and sediments within the Linda Moraines were shown to have reversed polarity (Barbetti and Colhoun, 1988), and therefore yielded an age of >0.78 Ma. Furthermore, pollen assemblages from an underlying paleosol contain abundant *Nothofagus brassii*, a taxa only known from pre-Pleistocene deposits in Tasmania. Thus, the Linda Moraine can be assigned an early Pleistocene age on the basis of magnetostratigraphy, biostratigraphy, and geochronology.

These two examples are a timely reminder that multiple correlation criteria should be employed wherever possible.

Aminostratigraphy and Amino Acid Dating of Bone

In the absence of independently dated calibration samples, the extent of amino acid racemization (usually given as a D/L ratio) in fossil shell material has proved a powerful tool for stratigraphic correlation (referred to as aminostratigraphy). However, in many cases, reliable calibration allows conversion of D/L ratios into numerical age estimates. Examples include marine bivalves in shoreline deposits (Hearty et al., 1986; Murray-Wallace, 1995), nonmarine mollusks (Bowen et al., 1989), and eggshell (Miller et al., 1999).

Dating the first human colonizations of North America is a controversial topic, with many archaeologists favoring a 'late' arrival, in the range 12–13 ka, although significantly older ages have been postulated. Some of the critical human fossils were found in the 1920s and 1930s in California and like many other human fossils, their stratigraphic context was not well documented. Thus, any age information had to come from direct dating of the bones rather than dating of associated materials.

The development of amino acid racemization (AAR) dating in the late 1960s offered the possibility of directly dating fossil bones that were previously unable to be dated by radiocarbon. The main advantage of AAR, at the time, was the small sample size (a few grams of bone) and an extended age range (~ 100 ka) relative to radiocarbon. Based on the extent of

aspartic acid racemization in bone, Bada et al. (1974) reported ages up to 48 ka for several skeletons from California, generating an intense controversy about the validity of the ages and the antiquity of humans in America. As AAR dating requires knowledge of the rate of racemization, calibration was obtained using one bone that had previously yielded a radiocarbon age of $17\,150 \pm 1470$ years BP on its collagen fraction.

Subsequently, the same skeletons were dated by U/Th and AMS radiocarbon, yielding ages <10 ka (Bada et al., 1984). In particular, the amino acid extracts from the calibration sample, collagen from which had previously been dated at ~ 17 ka, gave an AMS radiocarbon age of 5100 ± 500 years. Naturally, using the revised, younger age of the calibration sample considerably reduced the AAR age estimates. The combined results of the U/Th, AAR, and AMS radiocarbon measurements indicate Holocene ages for the skeletal material and reinforce the necessity for cross-checking of ages using multiple techniques. Furthermore, had the field stratigraphy been documented at the outset, the erroneous ages may well have been identified earlier and much of the controversy avoided.

The Timing of the Last Interglacial from Shoreline Deposits

The Last (Eemian) Interglacial was the last time, prior to the Holocene that the eustatic sea level was at or slightly higher than the modern level, and the last time when ice volumes and global climate were similar to the present. Thus, shoreline deposits of the last interglacial age are widely preserved, close to

the present sea level on tectonically stable coasts, and valuable as a global stratigraphic marker. On tectonically active coasts, the height of the Last Interglacial shoreline is an excellent datum for calculating uplift rates (Figure 3).

Uranium-series ages on fossil corals from the last interglacial reefs are generally in the range of 135–115 ka. However, the timing of the onset and the duration of the last interglacial varies widely from place to place, and a detailed reconstruction of sea-level changes during this time interval remains elusive. Age variations might be a consequence of several factors, including dating uncertainties and isostatic and tectonic effects, as well as uncertainties associated with paleo-sea-level indicators.

In a careful study, utilizing TIMS U-series dating of corals from Western Australia, Stirling et al. (1998) concluded that coral reef growth started at 128 ± 1 ka along the entire Western Australian coastline, when the relative sea level was at least 3 m above the present level. From a regressive reef sequence at Mangrove Bay (Figure 4), the termination of the last interglacial period occurred at 116 ± 1 ka, but the main period of reef building was between 128 and 121 ka. All samples came from sites that were considered to be tectonically stable and that were not significantly affected by glacio-isostatic adjustments, being remote from former ice sheets. To eliminate the possibility of reworking, coral samples were collected in growth position. Samples were also checked for possible diagenesis using a stringent set of criteria, including lack of evidence for recrystallization ($<1\%$ calcite), low ^{232}Th concentration,

Figure 3 Uplifted coral terraces at Sialum on the Huon Peninsula, Papua New Guinea. The Last Interglacial reef complex is at an elevation of ~ 180 m, indicating a mean uplift rate of ~ 1.5 m/ka. Inset shows sea-level record of the last 140 ka as reconstructed from Huon Peninsula and deep-sea core data. Figure 4 Distribution of *Anadara trapezia* in Australia and New Zealand. Photo shows specimens of *A. trapezia* (ribbed shells) and *Anapella cycladea* (smooth shells) from Last Interglacial shoreline deposits (Glanville Formation) at Victor Harbour, South Australia (see Murray-Wallace et al., 2000).

typical U concentration (~ 3 ppm), and initial $^{234}\text{U}/^{238}\text{U}$ ratio in the modern range of $149 \pm 4\%$.

Identification and dating of last interglacial shorelines in extratropical regions of Australia and elsewhere are hampered by a lack of corals, which have proved to be the most reliable dating medium. Uranium-series dating of fossil mollusk shells has been widely tried, but it is considered to be unreliable because of its open system behavior (e.g., Kaufman et al., 1971). Living mollusk shells contain very low uranium concentrations, typically a few ppb. However, fossil mollusks contain significantly higher U, typically in the ppm range, indicative of postmortem U uptake and leading to age underestimates. Eggins et al. (2005) used laser-ablation multi-collector ICPMS measurements on a robust mollusk shell (*Anadara trapezia*) of the last interglacial age to investigate the nature of U uptake. A profile of measurements 5 mm long from the interior to the exterior of the shell showed increasing U concentrations and $^{230}\text{Th}/^{234}\text{U}$ ratios toward the exterior, consistent with progressive U uptake. The oldest apparent ages (~ 120 ka), obtained at the exterior surface, are consistent with the last interglacial age, but significantly younger apparent ages (~ 60 ka) were obtained from the interior of the shell.

On the east coast of Australia, the last interglacial coastal sand barriers contain abundant fossil kauri (*Agathis* sp.) logs, which have yielded radiocarbon ages on different extracts from the wood that range from background to as young as 11 ka (Chappell et al., 1996). The true age of the barriers (~ 120 – 130 ka) is established from U/Th dating of fossil corals at one site, so the radiocarbon ages are erroneously young, reflecting variable amounts of contamination. In the 1960s and early 1970s, radiocarbon dating of shoreline deposits from many parts of the world indicated that sea level was within 10 m of the present level in the age range of 20–40 ka. However, Thom (1973) concluded that almost all these studies were in error either because the radiocarbon ages were wrong or because they had been incorrectly associated with sea-level events.

Biostratigraphy and aminostratigraphy are important for identifying the Last Interglacial shoreline in the Australasian region, with many sites in southern Australia and New Zealand containing the warm-water estuarine bivalve, *A. trapezia* (Murray-Wallace et al., 2000) – Figure 4. Similarly, in the Mediterranean, the Last Interglacial is recognized by the presence of the warm water ‘Senegalese’ fauna, including the distinctive gastropod, *Strombus bubonius*, coupled with aminostratigraphy, which is calibrated by U/Th dating of corals (Hearty et al., 1986).

The Demise of the Australian Megafauna

Most of Australia’s largest mammals, reptiles, and birds (megafauna) became extinct in the late Pleistocene, but the causes are hotly debated. Possible causes include direct human hunting, alteration of vegetation by human burning, and climate change, particularly increased aridity leading into the Last Glacial Maximum. Roberts et al. (2001) reported OSL and U/Th burial ages for megafauna from 28 sites across Australia and concluded that the extinction occurred $\sim 46,400$ years ago, soon after the arrival of people in Australia. Thus, humans rather than climate change were implicated as the cause of the extinction. Their dating concentrated mainly on sites that contained articulated bones, to avoid problems with possible reworking of older material. Radiocarbon ages were not directly used because of known contamination problems in materials older than ~ 35 ka.

In a parallel study, Miller et al. (1999) reported more than 700 AAR ages on *Genyornis* eggshell from three different climatic regions of Australia and concluded that *Genyornis*, a large (ostrich-sized) flightless bird, became extinct at 50 ± 5 ka. Subsequently, Miller et al. (2005) concluded, based on $\delta^{13}\text{C}$ measurements of eggshell, that the extinction of *Genyornis* was the result of a dramatic change in available food sources, possibly caused by human burning of landscapes, which rapidly changed the vegetation from a drought-adapted mosaic of

trees, shrubs, and grasses to the modern fire-adapted desert scrub. Unlike *Genyornis*, the modern Australian emu (*Dromaius*) survived, probably because it was smaller and faster (and hence less attractive as a hunting target to humans), and also because it had a less specialized grazing diet that made it more adaptable to the vegetation changes. A notable feature of these studies by Miller et al. (1999, 2005) is that the majority of fossil eggshell fragments were collected from modern deflation hollows in sand dunes, where the eggshell occurred as a surface lag deposit (Figure 5). In other words, little stratigraphic context was available, nor was it necessary, to document the demise of *Genyornis* because they were able to date the fossils directly.

The study by Roberts et al. (2001) has been criticized because they excluded evidence for megafauna survival well after 46 ka, including many archaeological sites, which, inevitably, contain disarticulated remains of animals that were hunted (Johnson, 2005). However, if the abundance of a megafauna species was very low and the species was being actively sought out by hunters, then archaeological sites would likely have a much greater chance of recording their presence than nonarchaeological sites such as caves and swamps that are passive, a chance accumulators of bones. Johnson (2005) listed 13 sites with evidence indicating the possible survival of megafauna after 46 ka, all of which contained disarticulated remains, and the majority of which contained stratigraphic evidence of overlapping human occupation. Furthermore, there was a significant correlation between body mass and age, with smaller species generally surviving longer than larger species. Johnson (2005) therefore concluded that while the abundances of all elements of the megafauna were reduced to drastically low levels around 50 ka, some species may have persisted in very low numbers over restricted geographic ranges, and the final extinction of remnant populations may have been spread over a comparatively long period (up to 30 ka) after this event.

The demise of the Australian megafauna highlights some limitations that are common to all biostratigraphic correlations which use first and last appearance datums for correlation. First, when a species or a group of species are present in very low abundance, appearance datums will be very dependent on geographic range, and second, the preservation potential of fossils will be very low. It also highlights the challenge of dating by association which is common to much of Quaternary

stratigraphy. How do we know that the material being dated is the same age as the material we want to know the age of? Miller et al. (1999, 2003) circumvented this problem by directly dating the *Genyornis* eggshells, while Roberts et al. (2001) employed stringent criteria to ensure that their OSL ages represented the time of burial of the megafauna fossils they wanted to know the age of. Reworking of older fossil material into younger deposits is the curse of biostratigraphy, but by only dating articulated skeletons, Roberts et al. (2001) minimized its impact in their study. Recent direct dating of fossil megafauna teeth by combined ESR and U-series methods also provides a way of identifying reworked materials (e.g., Grün et al., 2010).

Marine–Terrestrial Correlation

During the nineteenth and early twentieth centuries, Quaternary stratigraphy was largely founded on the study of continental deposits, particularly glacial deposits. At the same time, shoreline deposits provided links to the oceanic realm. However, in the second half of the twentieth century, and since then, the retrieval of deep ocean sediment cores has resulted in a major shift in focus and a revolution in Quaternary stratigraphy.

In particular, the oxygen isotope stratigraphy of deep-sea cores provided a climatostratigraphic template against which almost all other stratigraphies could be compared. This came about largely because the deep-sea sediment record is more continuous than most long continental records, with the exception of the Chinese loess record. Equally important was the development of the astronomically calibrated timescale for oxygen isotope stages (e.g., Lourens et al., 1996). Thus, marine–terrestrial correlation has become a significant part of Quaternary stratigraphy, some examples of which are discussed in the following paragraphs.

Wanganui Basin

Wanganui Basin in the North Island of New Zealand contains the most complete, on-land, shallow-marine record of Quaternary climatic and sea-level change yet described (Figure 6). Sedimentation generally kept pace with basin subsidence, resulting in a 3 km thick basin fill of dominantly coastal and shallow marine sediments over the last 3.6 Ma. The basin fill comprises cyclic, unconformity-bound strata, mostly representing environments located landward of the contemporaneous shelf edge. Gentle neotectonic upwarping of the eastern margin has produced on-land exposures through as many as 47 superposed cyclothem deposited since Marine Isotope Stage 104 (~2.6 Ma). Nearly all of the 41 and 100 ka Pleistocene sea-level cycles are represented by individual depositional sequences comprising transgressive (TST), highstand (HST), and regressive system tracts (RST). In general, major sedimentary facies within the basin fill were deposited in a range of coastal plain, shoreface, and shelf marine environments during the rise, highstand, and falling part of each glacioeustatic cycle. Thus, the Wanganui stratigraphic record represents deposition dominantly during odd-numbered (interglacial) isotope stages. Glacial stages are represented by regressive shoreline facies that are truncated above by surfaces of marine planation and bioerosion, and that mark both cyclothem and sequence boundaries.

Southward migration of the basin depocenter and gentle marginal upwarping have not only resulted in excellent exposures of the basin fill, but have also led to the development of an extensive flight of marine terraces around the basin margin. The terraces were formed during each interglacial from ~680 ka (MIS17) to ~60 ka (MIS3), with overlying loess beds representing each glacial stage from MIS12 to MIS2 (Naish et al., 1998; Palmer and Pillans, 1996; Pillans, 1983). This direct stratigraphic association between loess and marine terrace sequences is unusual and allows unequivocal marine–terrestrial correlation (Pillans, 1994a,b) – **Figure 7**. Pollen analyses of interbedded peats, as well as plant phytoliths recovered from the loess, allow the vegetation history to be established and contribute to paleoclimate reconstructions.

An integrated chronology for the basin has been developed from radiometric ages of tephras, magnetostratigraphy, sequence stratigraphy, biostratigraphy, and cyclostratigraphic correlation to the oxygen isotope stratigraphy of deep-sea cores east of New Zealand (Pillans et al., 2005). However, none of these techniques would have been successful without careful field mapping and lithological description of stratigraphic sections.

Rangitawa Tephra: A Widespread Marker Bed in the South West Pacific Region

The Taupo Volcanic Zone (TVZ) in New Zealand is the source of some of the largest Quaternary volcanic eruptions in the world – Machida (2002) lists 12 tephras with volumes >100 km³ that

were erupted from the TVZ during the last 1.6 Ma, the last being the Taupo Tephra only 1800 years ago.

The Rangitawa Tephra (345 ka) was perhaps the largest eruption from the TVZ in the last 500 ka, probably associated with the eruption of the Whakamaru group ignimbrites (Kohn et al., 1992). First identified in the early 1950s in Wanganui Basin, Rangitawa Tephra is found throughout the central and southern North Island, in the South Island, and in deep-sea cores more than 1000 km from its source. Thus, the tephra is a valuable widespread mid-Pleistocene marker bed that enables marine–terrestrial correlations throughout the New Zealand region. Pillans et al. (1996) reported 51 independent numerical age estimates for Rangitawa Tephra, in the range 176–456 ka, only 15 of which were considered reliable. The weighted mean age of nine reliable fission track age determinations was 345 ± 12 ka, in excellent agreement with a weighted mean age of 340 ± 7 ka for two reliable astronomically calibrated age estimates from deep-sea cores.

At the well-documented Rangitatau East section (**Figure 7**) in Wanganui Basin, the tephra occurs in the upper part of Loess L10 with a well-developed paleosol immediately above. At the Mt Curl section (**Figure 8**), further east, the tephra is underlain by loess and overlain by interglacial coastal dune sand. Thus, the tephra is interpreted to have fallen at the end of a glacial period, consistent with pollen analyses of associated sediments at other sites (Kohn et al., 1992), and consistent with its position in two deep-sea cores close to the MIS 10/9 boundary (**Figure 8**).

Figure 7 Stratigraphy and chronology of loess and tephras at Rangitatau East section, Wanganui Basin, and relationships to marine terraces (Palmer and Pillans, 1996).

Figure 8 Stratigraphy and correlation of Rangitatau Tephra in marine and terrestrial sequences, New Zealand. Reproduced from Kohn BP, Pillans B, and McGlone MS (1992) Zircon fission track age for middle Pleistocene Rangitatau Tephra, New Zealand: Stratigraphic and paleoclimatic significance. *Palaeogeography, Palaeoclimatology, Palaeoecology* 95: 73–94. Photo shows Rangitatau Tephra underlying MIS 9 coastal sand dune at Mt Curl section, Wanganui Basin.

In the late 1970s and early 1980s, the tephras identified in Rangitatau East and Mt Curl sections in Wanganui Basin were considered to represent separate eruptions because their fission track ages were significantly different (~ 370 ka vs. ~ 240 ka, respectively). However, the two tephras had very similar field character, mineralogy, and glass shard chemistry and were nowhere identified in the same section. Were they the same tephra or were they two very similar tephras of different ages? This question, which is often asked in tephrostratigraphy, is not always easily answered for the very reason that tephras erupted from the same source can indeed be very similar in character. The question was answered when it was found that the early (pre-1981) glass ages were too young because of uncorrected track annealing and uncertainties in estimation

of neutron dose measurement, while the zircon ages were too young because of underetching (Kohn et al., 1992; Pillans et al., 1996). Subsequent glass fission track ages were corrected for track annealing using the isothermal plateau technique (Westgate, 1989), and zircons were redated with standardization of etching conditions and use of the zeta calibration technique to overcome uncertainties in decay constants and neutron fluences (Pillans et al., 1996).

The Matuyama/Brunhes Boundary

The last major polarity reversal of the Earth's magnetic field, known as the Matuyama/Brunhes polarity transition or reversal, has long been used as a major chronostratigraphic marker

in Quaternary studies. The Matuyama/Brunhes boundary (MBB) is widely identified in both marine and continental sequences and is also a key time marker for the chronology of human evolution (Pillans, 2003).

As summarized by Pillans (2003), the MBB is widely used to define the Lower–middle Pleistocene boundary ever since the Burg Wartenstein Symposium ‘Stratigraphy and Patterns of Cultural Change in the middle Pleistocene’ held in Austria in 1973 recommended that “The beginning of the middle Pleistocene should be so defined as to either coincide with or be linked to the boundary between the Matuyama Reversed Epoch and the Brunhes Normal Epoch of paleomagnetic chronology” (Butzer and Isaac, 1975).

The age of the MBB is independently established at ~780 ka from astronomical calibration of deep-sea isotope records (Tauxe et al., 1996) and $^{40}\text{Ar}/^{39}\text{Ar}$ dating of basaltic to andesitic lavas that were erupted during the polarity transition (Singer and Pringle, 1996). However, some age estimates are up to ~790 ka (e.g., Berger et al., 1995; Hou et al., 2000). While the 10 ka spread in age estimates might be partly explained by differences in intercalibration standards for $^{40}\text{Ar}/^{39}\text{Ar}$ dating (Renne et al., 1998), it should be noted that the MBB transition was not an instantaneous change in magnetic polarity but may have lasted several thousand years (Singer and Pringle, 1996; Tauxe et al., 1996). Thus, a single, precise age for the MBB is somewhat unrealistic and, indeed, is not necessary for many stratigraphic applications.

Well-defined paleomagnetic records in deep-sea sediments indicate that the MBB is located in interglacial Marine Isotope Stage 19 (Tauxe et al., 1996) – Figure 9. However, its inferred position in continental sediments is somewhat more variable, ranging from glacial MIS 20 to interglacial MIS 19 in Asian and European loess sequences. This discrepancy was analyzed by Zhou and Shackleton (1999), who concluded that the measured position of the MBB in loess sequences was misleading. Their conclusion was based on the stratigraphic position of a layer of

microtektites from the Australasian tektite field (see below), which occurred above the MBB in loess, but below the MBB in marine cores. They argued that there was a variable delay in remanence acquisition in the loess as a result of postdepositional weathering processes, which resulted in a downward displacement of the position of the MBB. More recently, Liu et al. (2008) have questioned the identification of Australasian microtektites in the Chinese loess and argued that the true position of the MBB in Chinese loess is in the upper part of soil S8, which in turn should be correlated with the upper part of MIS 19.

In strongly weathered, generally unfossiliferous Quaternary continental sequences in Australia, the MBB is one of the most important chronostratigraphic markers in the Lower–middle Pleistocene (Figure 9). However, the primary component of magnetic remanence is variably affected by chemical weathering, resulting in a secondary weathering-induced remanence that may completely or partially mask the primary component. Thus, there may be an apparent downward displacement in the position of the MBB as a result of Brunhes normal overprinting. In such settings, where strata are strongly weathered and secondary magnetic overprints are suspected, the presence of reversed polarity remanence provides a minimum age of 780 ka (Pillans, 2003).

Tektites

Tektites (from the Greek word ‘tektos,’ meaning molten) are glassy objects produced from melted crustal rocks that are caused by large hypervelocity meteorite impacts on sediments (Jackson, 1997). On impact, molten blobs of rock are ‘splashed’ into the atmosphere and cooled during flight to form shapes that include spheroid, elliptical, and dumbbell shapes, depending on the degree of rotation. Most tektites also have secondary surface features that are consistent with aerodynamic ablation during hypersonic flight.

Figure 9 The Matuyama/Brunhes boundary (MBB) links marine and terrestrial sequences in Australasia, demonstrating that major climatic changes across the Mid-Pleistocene transition were broadly synchronous (redrawn from Pillans, 2003). However, the major arid shift was significantly earlier at Lake Amadeus (photo: J. Magee).

About 800 000 years ago, a large extraterrestrial impact occurred in southeast Asia, producing tektites, microtektites (<1 mm size), and impact debris, which are found over more than 10% of Earth's surface (Schnetzler and McHone, 1996), including much of Australia and surrounding oceans (Figure 10). The distribution, size, and concentration of tektites and microtektites indicate a likely impact site somewhere in southern Laos or Thailand, but the location of the impact site has not yet been discovered.

Like tephra, tektites are important chronostratigraphic markers, because they represent almost instantaneous events, can be directly dated by methods such as fission-track, K/Ar, and $^{40}\text{Ar}/^{39}\text{Ar}$, and can be correlated over large distances, including both marine and terrestrial deposits.

Although there has been considerable debate concerning the age of the Australasian tektites, their age is now firmly established through magnetostratigraphy of deep-sea cores, in which microtektites occur just prior to the Matuyama/Brunhes polarity transition (Schneider et al., 1992), as well as direct laser fusion $^{40}\text{Ar}/^{39}\text{Ar}$ dating of tektite glass (Izett, 1992; Hou et al., 2000). The most accurate and precise age for the tektites is the weighted mean age of 803 ± 3 ka reported by Hou et al. (2000). Previously, a number of field studies supported a late Pleistocene age in the range 5–25 ka (e.g., Lovering et al., 1972), but these occurrences are now considered to represent reworking into younger sediments (e.g., Fudali, 1993; Shoemaker and Uhlherr, 1999). There has long been speculation that the impact

may have triggered the M/B reversal. However, the estimated time (12–15 ka) between the impact and the reversal appears to be too long for a causal link between the two events. Impact glass (Darwin Glass) in western Tasmania, which yields an $^{40}\text{Ar}/^{39}\text{Ar}$ age of 816 ± 7 ka (Lo et al., 2002), appears to be from a separate impact during the same time period.

Even in deposits where reworking is suspected, the presence of tektites provides a maximum age of 800 ka for the enclosing sediment. For example, waterworn tektites have been found in diamond-bearing alluvial gravel terraces some 25 km downstream of the Argyle diamond mine in northwestern Australia (Fudali, 1993), indicating a maximum age of 800 ka for the terraces. Australasian microtektites are also present in Chinese loess sequences, where their presence as a discrete layer was used to correct the misleading position of the Matuyama/Brunhes polarity transition (Zhou and Shackleton, 1999) – Figures 10 and 11. Australasian tektites associated with Acheulean-like stone tools in South China yield an $^{40}\text{Ar}/^{39}\text{Ar}$ age of 803 ± 3 ka, thus making them the oldest known large cutting tools in East Asia (Hou et al., 2000).

Chinese Loess

The classic loess sequences of China (Figure 11) are arguably the most complete continental record of the Quaternary. Initially, magnetostratigraphy provided the overall chronology,

Figure 10 (a) The Australasian tektite field. Reproduced from Prasad MS, Gupta SM, and Kodagali VN (2003) Two layers of Australasian impact ejecta in the Indian Ocean? *Meteoritics and Planetary Science* 38: 1373–1381. (c,d) Reproduced from Schneider DA, Kent DV, and Mello, GA (1992) A detailed chronology of the Australasian impact event, the Brunhes-Matuyama geomagnetic polarity reversal, and global climatic change. *Earth and Planetary Science Letters* 111: 395–405.

Figure 11 Loess/paleosol sequence at Luochuan section, China, and contrasting positions of the Matuyama/Brunhes boundary in Luochuan loess versus deep-sea cores. Reproduced from Zhou LP and Shackleton NJ (1999) Misleading positions of geomagnetic reversal boundaries in Eurasian loess and implications for correlation between continental and marine sedimentary sequences. *Earth and Planetary Science Letters* 168: 117–130.

which was later supplemented by a higher-resolution time scale based on magnetic susceptibility variations (see Kukla (1987) and references therein). A cycle-by-cycle correlation of the Chinese loess/paleosol sequence, down to the level of the Red Clay (~2.6 Ma), with the marine isotope record was first accomplished by Kukla (1987). Hovan et al. (1989) established direct links between Chinese loess and the marine isotope record by measuring the dust content of a marine core in the North Pacific. Most recently, Sun et al. (2006) have tuned the grain size records of two Chinese loess sections to orbital parameters to provide an independent astronomical timescale for the loess records, allowing improved correlation to the marine isotope record.

Pollen Analysis of Marine Sediments

Reconstruction of vegetation changes based on pollen analysis has long played a central role in reconstructing Quaternary climates. However, while detailed ice-core and marine isotope records, in particular, have provided new insights into global climate changes, there is a dearth of well-dated, long, continuous terrestrial pollen records that can be used to examine the detailed phase relationships between these and other

paleoclimate time series. Commonly, the chronology for terrestrial pollen records has been established by transferring the marine isotope timescale, on the assumption that there is synchronicity of certain events between the two records (e.g., Tzedakis et al., 1997), but clearly the best approach is to directly analyze both pollen and oxygen isotopes in the same marine sediment core (e.g., Heusser and Shackleton, 1979; Mildenhall et al., 2004).

A high-resolution pollen and oxygen isotope record of the Last Interglacial from deep-sea core MD95-2042, located off the coast of Portugal, indicates that the full interglacial conditions on land (as evidenced by expansion of forest vegetation) lasted from 126 to 110 ka, whereas full interglacial marine conditions (MIS 5e) lasted from 132 to 115 ka (Shackleton et al., 2003). In other words, there is an implied lag of 5–6 ka between the terrestrial and marine records at this site. Tzedakis (2005) has noted that during the last two interglacials, major tree population expansion in southern Europe was closely associated with the peak in Northern Hemisphere June insolation at 65°N, and less influenced by the timing of deglaciation. Given that different vegetation communities are limited by different bioclimatic parameters, this association is unlikely to be universally applicable.

A 350 ka high-resolution pollen record from DSDP Site 594 (Figure 6), ~250 km east of the South Island of New Zealand, was obtained by Heusser and van de Geer (1994). Their study was significant because it demonstrated that, within the limits of sampling resolution (~2.4 ka), New Zealand terrestrial vegetation changes covaried with the global oxygen isotope record from the same core. In other words, Northern and Southern Hemisphere climate records were essentially synchronous. Nelson et al. (1985) had previously reached the same general conclusion from their study of lithological variations in the core from DSDP Site 594 – increased terrigenous silt inputs from expanded glaciers in the South Island corresponded with times of enriched $\delta^{18}\text{O}$, indicating that alpine glaciations in New Zealand were in phase (± 3 ka) with global climate changes over the past 750 ka.

Conclusion

The stratigraphy and correlation of continental glacial deposits dominated Quaternary science for many years, culminating in the widespread application of the so-called four glaciation model, which was based on classical glacial sequences in the European Alps. When oxygen isotope stratigraphy of deep-ocean cores provided evidence for many more glacial intervals in the Quaternary, the incompleteness of the continental record was revealed. A lack of reliable ages beyond the range of radiocarbon dating also imposed limitations on glacial

stratigraphy on-land, whereas the glacial cycles in marine records were more readily dated.

The rise to primacy of the marine isotope stages (MIS) as the global template for Quaternary stratigraphy can be traced to two seminal papers. The first was the study of oxygen isotope variations in core V28-238 from the western equatorial Pacific (Figure 12) by Shackleton and Opdyke (1973), who famously predicted that ‘it is highly unlikely that any superior stratigraphic subdivision of the Pleistocene will ever emerge.’ The second was the paper by Hays et al. (1976), which demonstrated the control of orbital perturbations and paved the way for astronomical tuning.

Another significant paleoclimatic archive that has become available in recent years is the highly detailed ice cores from Antarctica, Greenland, and various smaller ice caps. The longest and oldest ice cores are from Antarctica and extend back over 800 000 years (EPICA Community Members, 2004; Luthi et al., 2008). A detailed study of such cores is revolutionizing our understanding of global climate change in the Quaternary, in much the same way that deep-sea cores did previously.

Ice cores and deep-sea cores notwithstanding, Quaternary stratigraphy of continental sequences remains central to the discipline of Quaternary research, including the history of human evolution (cf. deMenocal, 2004). One challenge remains, and that is, to establish precise correlations between marine, ice, and continental archives using all methods of stratigraphic correlation. The global correlation chart (Figure 13) and recent results from precisely dated speleothems demonstrate that this challenge is being met (e.g., Cheng et al., 2009; Wang et al., 2001).

Figure 12 Analysis of deep-sea sediment cores, such as core V28-238 (Shackleton and Opdyke, 1973) revolutionized Quaternary stratigraphy in the 1960s and 1970s. Sir Nicholas Shackleton (1937–2006) was a leader in this research. Photo of Joides Resolution drilling ship courtesy of International Ocean Drilling Program, Texas A&M University.

Continental Biostratigraphy

Introduction

One of the most debated questions in geological sciences is what is the age. The age of a particular event, the age of a remarkable discovery, the age of a glaciations, the age of the hominines dispersal into Europe, or the extinction of, for instance, the woolly mammoth. There are different ways to solve questions about the age: to date the fossil record. A classical, widely used method is biostratigraphy, that is, the science of dating rocks and sediments using animal and plant fossils. The fact that during the Quaternary the continental flora and fauna almost constantly changed means that biostratigraphy for dating provides a good basis for correlation of stratigraphic sequences or events at one locality to those at another locality, for example, for correlation between Europe and Asia. However, biostratigraphy is a relative dating method and must be independently calibrated with numerical dating methods before numerical ages can be assigned to biostratigraphic zones or events.

The Quaternary Changes in Flora and Fauna

The rapid and continuous climatic changes during the Quaternary induced important changes in environmental conditions and available habitats. This is particularly the case in higher latitudes or in areas such as the western part of the North European plain, where the conditions are less diverse, in comparison to mountainous areas such as central Italy or the Balkan Peninsula. The forest vegetation, which dominates the flora of northwestern Europe during interglacial phases, disappeared during the cold stages and was replaced by the so-called Mammoth Steppe, treeless vegetation types which are 'analogous but not necessarily identical in plant composition to present-day's tundra, steppe, and alpine meadows.' The climatic changes that characterize the past 2.5 Ma of our geological history had a huge impact on the composition of the flora and fauna and on the distribution of species in particular at the higher latitudes. The composition of the Quaternary flora and fauna had undergone changes due to (a) the evolution of species, (b) the extinction of species, and (c) the dispersal or migration of species.

The Evolution of Species

The evolution of species is a natural phenomenon that can be observed in the entire geological history of the earth. The idea of evolution has been put forward by, for example, Darwin (1809–82) and Wallace (1823–1913) and are extensively described by Darwin in *The Origin of Species* (full title *On the Origin of Species by Means of Natural Selection, or the Preservation of Favoured Races in the Struggle for Life*) published on

24 November 1859. As stated by both scientists, natural selection is the base for evolution. Natural selection can take place if:

- (1) there is more offspring that can grow to adulthood;
- (2) there will be a struggle for survival among individuals;
- (3) in sexually reproducing species, no two individuals are identical. Variation is rampant;
- (4) much of this variation is heritable.

From this, one can infer that in a world of stable populations where each individual must struggle to survive, those with the 'best' characteristics will be more likely to survive, and those desirable traits will be passed to their offspring; and that these advantageous characteristics are inherited by following generations, becoming dominant among the population through time. This is natural selection that leads to the evolution of species that can be observed in the Quaternary fossil record.

Many different species show evolutionary changes during the past 2.5 Ma. However, there are also species with a long stratigraphical range that hardly evolve or do not evolve at all. This applies to nearly all plant species but also to, for example, mollusks, insects, amphibians, and, reptiles. Among the Quaternary mammals there are species that do not show clear evolutionary changes such as the Chiroptera or bats. Another example is the pygmy shrew *Sorex minutus*, a species that only shows some fluctuations in size during the past 2.5 Ma. The pygmy shrew is widespread in Europe and lives under different climatic conditions. It inhabits areas with good ground cover although it is uncommon in woodland. The Pleistocene climatic and inherent environmental changes influenced the geographical distribution of the species but hardly affected the morphology of the dentition and the skeleton of the species. The fossil record of the species does not show a clear evolution. This applies also to a number of forest dwellers such as the wood mouse *Apodemus sylvaticus*, squirrels (e.g., the red squirrel *Sciurus vulgaris*) and glirids (e.g., the garden dormouse *Eliomys quercinus* and the common dormouse *Muscardinus avellanarius*).

Fortunately, there are a large number of species that clearly evolve even in a relative short period as the Quaternary. The evolution is in some cases rather rapid, in others rather slow and not all the evolutionary changes occur in the same period of time. Some species mainly evolve during the early Pleistocene whereas others show clear changes during a later phase of the Quaternary. Remarkable is the fact that many species show comparable evolutionary changes. A general feature in the evolution is:

- (1) the increase in the height of the crown of the premolars; and
- (2) the increase of complexity of the enamel pattern of the premolars.

Both features are related to the adaptation to more abrasive nutrition. The deterioration of the climate led to the reduction

of woodland vegetation and an expansion of a more open habitat with a dominance of grasses. For many herbivores, this implies a change to more abrasive food.

Change in size is another feature that can be observed in a number of Quaternary species. Pleistocene wolverines show a remarkable increase in size during the middle Pleistocene. The same, however, less extensive, can be seen in wolves. Horses, on the other hand, increase in size during the early part of the middle Pleistocene whereas they reduce in size from the later part of the middle Pleistocene onwards. Changes in size are generally not unidirectional and are, therefore, not a good feature for biostratigraphical purposes. It can only be used in combination with other data.

Among the species that show a clear evolution during the Quaternary and are, hence, biostratigraphically relevant are the mammoths belonging to the lineage *Mammuthus rumanus*–*Mammuthus meridionalis*–*Mammuthus trogontherii*–*Mammuthus primigenius* and a large number of voles representing different vole-lineages.

Mammoth Evolution

Many paleontologists investigated the patterns and processes in the evolution of the Eurasian elephantids or mammoths and is hence, one of the best known lineages. Mammoth evolution began in Africa and during the late Pliocene mammoths migrated to Eurasia. The late Pliocene and Pleistocene fossil record indicates that the Eurasian mammoth underwent very significant changes: a shortening and heightening of the cranium and mandible (Figure 1), an increase in the relative height of the molars, an increase in the number of plates and thinning of the dental enamel (Lister et al., 2005). The earliest representatives of the European mammoth *Mammuthus rumanus* from the interval 3.5–2.5 Ma is characterized by upper M³ molars with 8–10 plates, a hypsodonty index (i.e., the height of the crown divided by the width × 100) of about 120 and an average thickness of the enamel of about 3.8 mm. The upper M³ of the most advanced representative of the mammoth lineage *Mammuthus primigenius* has 20–28 plates, an average hypsodonty index of about 200 and enamel with a thickness that ranges between 1.0 and 2.5 mm with an mean of about 1.6 mm.

Previously it was assumed that the transformation within the *Mammuthus rumanus*–*Mammuthus meridionalis*–*Mammuthus trogontherii*–*Mammuthus primigenius* lineage was gradual and more or less simultaneous across the species' range. However, recent investigations of the geographical variation across the whole of northern Eurasia indicated a more complex model (Lister et al., 2005). The transition between *Mammuthus rumanus* and *Mammuthus meridionalis* is still poorly known; the number of late Pliocene fossil remains is too limited. The early- and early middle Pleistocene *Mammuthus meridionalis* is better known. The species was widely dispersed in Eurasia and migrated to America during the early Pleistocene. The European fossil record indicated that the species hardly evolved despite the fact that the species occurred in the region for almost 2 Ma. In eastern Asia, probably in China, however, *Mammuthus meridionalis* evolved into *Mammuthus trogontherii* in the interval 2.0–2.5 Ma. *Mammuthus trogontherii* expanded its original range and spread to NE Siberia by 1.2 Ma and toward Europe around 1 Ma. In NE Siberia *Mammuthus trogontherii* began a transformation into *Mammuthus primigenius* as early as 700 ka. The European population of *Mammuthus trogontherii* also hardly evolved and only shows a reduction of size in the interval between 1 Ma and 200 ka. *Mammuthus primigenius* with its origin in NE Siberia invaded Europe during the late middle Pleistocene about 200 ka ago.

The Evolution of Voles

Rodents are well represented in the present-day fauna; nearly 40% of all living mammalian species are rodents. They represent a huge variety of animals including, for example, beavers, squirrels, marmots, hamsters, rats, mice, voles, lemmings, dormice, and porcupines. Voles are a rather recent branch of diminutive grazers in the rodent evolution. They arose from the hamster lineage during the late Pliocene and are with the about 100 extant species very successful since, in particular during the Quaternary. The evolution of the voles shows the occurrence of radiations leading to a number of different lineages. All these lineages show in principle the same type of evolution.

The first changes that can be observed are an increase in height of the crown. The brachiodont molars develop into hypsodont molars with high enamel-free areas or dentine

Figure 1 *Mammuthus* crania from (a) Liventsovka, Russia, ~2.3 Ma, type locality of '*M. gromovi*' (after Azzaroli, 1977); (b) Chilhac, France (*M. meridionalis*, ~1.9 Ma, after Boeuf, 1990); (c) Upper Valdarno, Italy (*M. meridionalis* type locality, ~1.8 Ma, after Azzaroli, 1966); (d) Scoppito, Italy ('*M. meridionalis vestinus*', ~1.2 Ma, after Maccagno, 1962); (e) Cherny Yar, Russia, type of '*M. trogontherii chosaricus*,' after Dubrovo, 1966); (f) Debica, Poland (typical *M. primigenius*, after Kubiak, 1980). Scale bar 50 cm. Note the apparent increase in cranium height between (b) and (c). Reproduced from Lister AM, Sher A, van Essen H, and Wei G (2005) The pattern and process of mammoth evolution in Eurasia. *Quaternary International* 126–128: 49–64.

tracts. The increase of height of the crowns leads to a delay in the formation of roots, an evolution that finally results in voles with molars without roots. A second feature that can be observed in the evolution of voles is the development of crown cement in a number of the lineages. Crown cement occurs in the reentrant angles of the hypsodont molars. In addition, different lineages show an increase in the length as well as an increase in complexity of the posterior upper molar (M^3) and the anterior lower molar (M_1).

Another general feature that can be observed in different lineages are changes in the differentiation of the thickness of the enamel. The occlusal surface of the molars of voles shows a number of dentine field covered with enamel at the outer side. The anterior enamel edge of the salient angles of the lower molars is concave, the posterior convex. The concave edges occlude first during the longitudinal movement of the mastication; they are the so-called leading edges. The convex edges are the trailing edges. In a large number of living species, the enamel of the trailing edges is much thinner than that of the leading edges. The opposite can be observed in many more primitive species. The transition of trailing edges that are thicker to a situation in which the leading edges are relatively thicker is called the evolution in the differentiation in the thickness of the enamel.

The evolutionary changes described above do not occur simultaneously in the different lineages or within the lineages in the same region. The evolution of voles is a complicated story, studied by a large number of paleontologists. Because of the geographically wide range of the species, the often dominant occurrence in the Quaternary fossil record and the extremely quick evolution that can be observed in a number of lineages, voles are extremely important for Quaternary continental stratigraphy. In particular for Eurasia, the *Mimomys savini*, *Arvicola terrestris* lineage is important for the subdivision of the middle and late Pleistocene. *Mimomys savini*, a vole with rooted molars, is the ancestor of the living Water Vole *A. terrestris*. The species occurred in the European faunas during the late early and the early middle Pleistocene. The transition of populations of water voles with rooted molars to populations with more hypsodont, unrooted molars referred to the genus *Arvicola*, took place during the first half of the middle Pleistocene. This transition seems to be well established since populations with a small percentage of rooted molars are known from several localities in Germany, Italy, Czechia, and Russia. The genus *Arvicola* shows clearly a gradual evolution in the differentiation in the thickness of the enamel since its appearance during the early middle Pleistocene. The enamel differentiation appeared to be an important marker to indicate the evolutionary stage of *Arvicola* and hence the relative age of the fossil record.

The *Microtus (Allophaiomys)*–*Microtus (Microtus)* lineage is important for the biozonation of the later part of the early Pleistocene. The molars of that well-known lineage are already without roots. They first of all show changes in the differentiation of the thickness of the enamel and later, near to the end of the early Pleistocene, there is a huge radiation that leads to a number of different lineages such as the *Microtus (Stenocranius) hintoni*–*M. (St.) gregaloides*–*Microtus (St.) gregalis* lineage. For the early part of the Quaternary, one of the important lineages is the *Mimomys occitanus*–*Mimomys hajnachensis*–*Mimomys*

polonicus–*Mimomys pliocaenicus*–*Mimomys ostramosensis* lineage (Neraudeau et al., 1995) (Figure 2).

Extinction

Biostratigraphically important is also the extinction of species. Several examples demonstrate the global or local extinction of species. Well known are the late Pleistocene–early Holocene extinctions of mainly larger mammals that can be observed in almost every continent. In Eurasia, species such as *Ursus spelaeus*, *Mammuthus primigenius*, *Coelodonta antiquitatis*, *Equus hydruntinus*, and *Megaloceros giganteus* disappeared at the end of the late Pleistocene or the beginning of the Holocene. Extinction in the smaller mammal fauna of Eurasia can be observed in middle Pleistocene faunas. Species such as *Drepanosorex savini*, *Talpa minor*, and *Trogotherium cuvieri* are relicts from the early Pleistocene that became extinct during the middle Pleistocene.

Extinction is often preceded by a strong reduction of the geographical range of a species and a retreat to a refugial area. The late Pleistocene European rhinoceros species *Stephanorhinus kirchbergensis* and *Stephanorhinus hemitoechus* show a progressive southward contraction of their geographical range before getting extinct before the Late Glacial Maximum (Stuart, 1993, 2005; Stuart et al., 2004).

Migration and Dispersal of Species

The migration of mammal species is certainly the major factor in the changes of composition of the Quaternary faunas in a specific region. These migrations are first of all caused by the alternation of the available habitats due to the changes in climate and environment (van Kolfschoten, 1995). Eurasian cold stage faunas from the last and penultimate glacial period are characteristic and rather well known; species such as *Dicrostonyx gulielmi*, *Lemmus lemmus*, *Mammuthus primigenius*, *Coelodonta antiquitatis*, and *Rangifer tarandus* expanded their range southwards and occur together with species which prefer a more steppic environment such as ground squirrels (*Spermophilus undulates*) and hamsters (*Cricetulus migratorius* and *Cricetus cricetus*) that expanded their geographical range north and westwards.

A rise in temperature led to more distinct steppic conditions in the lower latitudes. These steppic conditions resulted in the increase of the relative number of steppe elements. Lemmings and other cold stage indicators withdrew northwards and species such as the steppe lemming *Lagurus lagurus* migrated westward and invaded Northwestern Europe. A rise in temperature is followed in certain areas such as the North European plain by an increase of oceanic influences. That results in a climate, which induces a re-establishment of forests with thermophilous broad-leaved and coniferous trees and the return of forest dwellers such as glirids (*Eliomys quercinus*, *Muscardinus avellanarius*), wild boar (*Sus scrofa*), and cervids (*Cervus (Dama) dama* and *Capreolus capreolus*) (van Kolfschoten, 1992).

This general picture of alternating species, more or less the same species that ‘comes and goes’, is applicable to the late middle and late Pleistocene and may be also to the earlier cold stages. However, one can distinguish a migration of species that is more or less independent of, and not only the result of

Figure 2 Phyletic gradualism in the *Mimomys occitanus*–*M. ostromosensis* lineage, showing the major evolutionary trends: increased hypsodonty related to a higher linea sinuosa; appearance of cementum in the re-entrant angles, and disappearance of the enamel islet. Continuous growth only occurs between *M. savini* and *A. terrestris* cantiana (after Chaline, 1987, modified). Reproduced from Neraudeau D, et al. (1995) Plio-Pleistocene water voles. *Palaeontology* 38(1): 77–85.

climatic change. The contemporary migration of a number of species characterizes the so-called major dispersal events. In addition, there are also incidental immigrations of single species. The woolly rhinoceros *Coelodonta antiquitatis*, for example, has its origin in Asia and invaded Europe during the middle Pleistocene, together with other cold stage faunal elements. The species is, since its appearance, a permanent element of the European cold stage faunas. The straight-tusk elephant *Elephas (P.) antiquus* invaded North Western Europe for the first time during the early middle Pleistocene and occurs during every interglacial period ever since. *Hippopotamus amphibius* also invaded Europe during the early middle Pleistocene, most probably during the same warm phase in which *Elephas (P.) antiquus* appeared. However, *Hippopotamus* did not return until the late Pleistocene (Eemian), after its withdrawal at the end of the early middle Pleistocene.

Another aspect is the migration and dispersal at subspecies level; the migration and dispersal of populations to areas which were inhabited by the same species. Tracing these migrations demands significant morphological differences between the 'new' population and the 'old' one, as is the case between the Late Saalian and Eemian *A. terrestris* populations of Northwestern Europe. The gradual change in differentiation of the enamel is interrupted and shows an important

fluctuation at the Saalian–Eemian transition. An explanation of this feature is the invasion of less derived populations. *A. terrestris* disappeared from the northern areas which were covered by inland ice and along the edge of the inland ice shield during the Late Saalian. The re-immigration of that area took place through the invasion of less-advanced populations which survived in areas located more to the south-(east). The presence of more primitive features in southern populations during the Pleistocene is very plausible since it has been demonstrated that the living *Arvicola* populations also show a strong morphological cline in the development of the enamel differentiation. The southern populations are in this aspect much more primitive than the northern populations (van Kolfschoten, 1992).

Biostratigraphical Subdivision of the Quaternary

Changes in the composition of the Quaternary mammalian fauna form the base for a biostratigraphical subdivision. In particular, as these changes are rapid and can be traced in a geographically extensive area the presence of a certain species, its evolutionary stage, or (although restricted) the absence of a species, can be used for dating deposits. No absolute

age-estimation but the indication of a relative age; dating in the sense of older than, or younger than, or about the same age.

The extensive and well-investigated Quaternary mammalian fossil record offers the possibility to divide the record into clusters and to establish a biostratigraphical subdivision or zonation of the Quaternary period (Figure 3). Each biostratigraphical unit or biozone is characterized by a distinct faunal assemblage. A number of mammal biozonations have been established by different authors. However, many of these zonations are not defined according to the official guide to stratigraphic nomenclature, and the terminology used by some authors is confusing. Furthermore, the application of several biozonations is geographically restricted. Two different biozonations are widely used in Quaternary biostratigraphy: the first one is based on the changes in the Eurasian larger mammal faunal community, the second one on the evolution in the smaller mammal assemblages. The coexistence of two different biozonations, one for the larger and one for the smaller mammalian record, is historically grown and is, for example, the result of specialization within the community of mammalian paleontologists.

Larger Mammal Biozonation

The widely adapted larger mammal biozonation is mainly based on the Italian fossil record and is established by Azzaroli and coworkers (Azzaroli et al., 1988). The Quaternary larger mammal faunas are divided into three assemblages: Villafranchian, Galerian, and Aurelian faunas (Figure 3). The Villafranchian is divided into an early, middle, and late Villafranchian; the transitions are marked by major events (Figure 4). The *Leptobos* event, indicating the appearance of species of the genus *Leptobos* in the Italian mammal faunas, marks the beginning of the Villafranchian. The first occurrence of *Mammuthus meridionalis* and *Equus stenonis*, the so-called elephant–*Equus* event, marks the transition of the early to middle Villafranchian. However, Rook and Martinez-Navarro (2010) have recommended against using the term ‘elephant–*Equus* event’ because true modern elephants (genus *Mammuthus*) and modern one-toed horses are recorded in some early Villafranchian faunas. The appearance of *Canis etruscus*, the ‘Wolf’ event, traditionally marked the middle to late Villafranchian transition, but it is now known that the expansion of wolf-like dogs across Eurasia was a diachronous event. A new term, ‘*Pachycrocuta brevirostris* event’ has recently been proposed because this hyaenid carnivore had a major continent-wide impact on faunal assemblages (Rook and Martinez-Navarro, 2010). The ‘end-Villafranchian’ dispersal event was originally described as a total faunal turnover, and massive extinctions and replacements mark the transition to the Galerian. However, it appeared that the original definition of the boundary between the Villafranchian and the Galerian is not applicable since the duration of the total faunal turnover took altogether about 0.5 Ma.

The Villafranchian starts long before the Quaternary, the oldest Villafranchian faunas have an age of about 3.5–3.6 Ma (Rook and Martinez-Navarro, 2010). The elephant–*Equus* event has an age of 2.5–2.6 Ma, the ‘*Pachycrocuta brevirostris* event’ age of 1.8 Ma. The stratigraphical position of the Villafranchian–Galerian transition is still problematic. Some authors put the transition at an age of about 1.1–1.2 Ma,

whereas others put the beginning of the Galerian close to the Brunhes/Matuyama boundary with an age of 0.78 Ma.

The Galerian–Aurelian transition is marked by the renewal of the fauna that coincides with the extinction of species such as those of the megacerine cervids of the *Megaceroides verticornis* group and *Megaloceros savini*, while modern taxa appear for the first time (Glozzi et al., 1997).

Smaller Mammal Biozonation

The smaller mammal biozonation that is widely used as a standard for the early and middle Pleistocene of Eurasia, is mainly a modified version of the Hungarian biozonation established by Kretzoi (1965). In this subdivision, three biozones are recognized for the Pleistocene period in the literature often erroneously referred to as ‘stages’: Villányian, Biharian, and Toringian. The Villányian faunas can be recognized by the dominance of voles of the genus *Mimomys* and the absence (or the occurrence in only a very low percentage) of voles of the genus *Microtus*. The Biharian faunas are characterized by a dominance of *Microtus* co-occurring with *Mimomys*. The Biharian biozone is divided into two substages: Lower and Upper Biharian. The disappearance of the subgenus *Microtus* (*Allophaiomys*) marks the transition from the Lower to the Upper Biharian. The Toringian biozone can be recognized by the *Arvicola*–*Microtus* assemblages. *Mimomys* is missing in Toringian faunas.

The chronostratigraphical age of boundaries of the biozones and hence, the chronostratigraphical ranges of the biozones are still a matter of debate. The Villányian started long before the beginning of the Quaternary at about 3.6–3.7 Ma. One of the most important abrupt changes in the smaller mammalian fauna took place during the transition of the Villányian to the Biharian biozone. The major faunal ‘turnover,’ in particular the reconstruction of the vole community, and the expansion of rootless voles characterized by the appearance of *Microtus* (*Allophaiomys*) (a group of voles, easily recognizable and well represented in the fossil record of the northern hemisphere), was dated until recently just after the Olduvai Event. This transition formed one of the strong ‘continental’ arguments to put the Plio–Pleistocene boundary near the top of the Olduvai. New data, however, indicate that the age of this faunal ‘turnover’ is not indisputable. Tesakov argues that this faunal ‘turnover’ took place long before the Olduvai Event. He dates the transition between 2.1 and 2.2 Ma. The transition between the Lower and the Upper Biharian is rather well dated. Most authors agree that *Microtus* (*Allophaiomys*) disappeared during or just before the Jaramillo paleomagnetic Subchron. The Biharian–Toringian transition is studied in great detail because the age of this transition is very important for dating the earliest Paleolithic sites in Europe. The first occurrence of the genus *Arvicola*, marking the beginning of the Toringian, dates around 0.5 Ma (van Kolfschoten, 1992; von Koenigswald and van Kolfschoten, 1996).

Additional Biozonations

The biozonations described above are mainly used by Eurasian continental biostratigraphers often next to regional zonations applicable in the area of investigation. There is no elaborated

(Continued)

Figure 3 Cont'd

Figure 4 Villafranchian chronology with range chart for selected European large mammals (from Rook and Martinez-Navarro, 2010). Newcomers from Africa shown in grey.

widely applicable biozonation of the continental floral record despite the fact that the impact of climate change during the Quaternary on the floral composition in most regions is huge and the stratigraphical range of many species is very fragmented and/or restricted. Floral species hardly show any evolution during the Quaternary and also the number of extinctions is restricted.

In the marine realm, there are a number of micropalaeontological zonations (Gibbard and van Kolfschoten, 2004; Lourens et al., 2004). Biozonations have been established for the fossil record of different microfossils: planktonic Foraminifera, calcareous nannofossils, diatoms, Radiolaria, and dinoflagellates. The planktonic Foraminifera biozonation and the calcareous nannoplankton biozonation are the major tools for subdividing marine sediments. The application of the other fossils is restricted to areas with specific conditions.

Concluding Remarks

Detailed studies of Quaternary deposits from the continental as well as from the marine environment resulted in a number of biozonations that play a role in the debate on dating and correlating strata. This is in particular the case for early Quaternary deposits. The use of biostratigraphical arguments is less relevant in younger deposits because the biozonation is too coarse for the detailed information one is looking for. The stratigraphical setting of middle and late Pleistocene strata in many cases offers the possibility to correlate them to regional stages such as the widely adapted northwest European Stages. Furthermore, there is a tendency to use the Marine Isotope

Stages as a reference in the debate on the age of continental finds, in spite of the very restricted number of direct correlations between continental and marine zonations.

Chronostratigraphy

Introduction

Chronostratigraphy is the part of stratigraphy that deals with the relative time relations of rock bodies, and a chronostratigraphic unit is a body of rock that was formed during a specified interval of geological time (Salvador, 1994). (The use of the term 'rock' to describe Quaternary strata that are unconsolidated or semiconsolidated may seem inappropriate at first sight. However, such usage is consistent with that adopted by the International Stratigraphic Guide (Salvador, 1994), and thus the term 'rock' is used here in its broadest sense.)

To facilitate international communication, the rock record of the earth is divided into standardized global chronostratigraphic units that make up the international geological time scale (GTS), managed by the International Commission on Stratigraphy (ICS). No GTS can be final, and the GTS is continually being refined as new data become available. The latest iteration is GTS2012 (Gradstein et al., 2012), which follows earlier iterations such as GTS2004 (Gradstein et al., 2004) GTS1989 (Harland et al., 1990) and GTS1982 (Harland et al., 1982). Chronostratigraphic subdivisions of the Cenozoic Erathem are shown in Figure 1.

Each chronostratigraphic (time-rock) unit of the GTS has an equivalent geochronologic (time) unit (Table 1). This dual hierarchy means that geologists refer to the rocks of the Pleistocene Series, but events in the Pleistocene Epoch. Similarly the terms 'early,' 'middle,' and 'late' are used as qualifiers for time units, while 'lower' and 'upper' are used as qualifiers for time-rock units. Zalasiewicz et al. (2004) have proposed to end the distinction between the two parallel classifications as a way of simplifying stratigraphic terminology. If their proposal were to be adopted, the terms Eonothem, Erathem, System, Series, and Stage would become redundant, in favor of Eon, Era, Period, Epoch, and (disputably) Age. And the qualifiers Upper and Lower would be made redundant in favor of Early and Late.

Global Boundary Stratotype Sections and Points

International subdivisions of the Phanerozoic part of the GTS are defined by their lower boundaries at Global Stratotype Sections and Points (GSSPs), often referred to as golden spikes. Note that a GSSP automatically defines the upper boundary of the underlying unit, thereby eliminating the possibility of overlap between adjacent units.

The principal requirements of a GSSP are

1. Location in a stratigraphically continuous section.
2. Good exposure and easy access for further study.
3. Precise definition at a lithological marker horizon.
4. The presence of multiple criteria for global correlation.

Typically, GSSPs have been defined in marine sedimentary sequences to make use of marine biostratigraphic markers for global correlation. However, this is not a necessary requirement. Similarly, for reasons of ease of access, until 2008, no GSSP had

been defined in drill core material. Both of these considerations were fully assessed when the Holocene GSSP was defined in a Greenland ice core (see Section 'Holocene Series').

Defining the Quaternary

The term Quaternary was introduced by the Italian mining engineer, Giovanni Arduino (1714–95), when he distinguished four orders of geological strata – Primary, Secondary, Tertiary, and Quaternary (Schneer, 1969). However, its definition and usage in the modern sense was not really established until the XVIIIth International Geological Congress in London in 1948. At this conference, it was resolved to select a stratotype for the Pliocene–Pleistocene boundary (stated as equivalent to the Tertiary–Quaternary boundary) and to “place the boundary at the first indication of climatic deterioration in the Italian Neogene succession (King and Oakley, 1949).” After consideration of several sections over the next three decades, the Vrica section in Calabria, southern Italy, was chosen and ratified as the Pliocene–Pleistocene stratotype (Aguirre and Pasini, 1985).

Unfortunately, the formal definition of the Quaternary was left unresolved when Aguirre and Pasini (1985: 116) stated that “The subject of defining the boundary between the Pliocene and Pleistocene was isolated from ... the status of the Quaternary within the chronostratigraphic scale.” The Quaternary was subsequently shown variously as a System above the Tertiary System (Salvador, 1994), or as a System above the Neogene System (Harland et al., 1990), but was never formally ratified as such. In each case, the base of the Quaternary (=base Pleistocene) was assigned an age of ~1.8 Ma.

When the Quaternary was shown as an informal climatostratigraphic unit in GTS2004, the international Quaternary community was incensed, and much discussion ensued (e.g., Aubry et al., 2005; Gibbard et al., 2005; Pillans and Naish, 2004). A significant outcome was that a majority of Quaternary scientists favored a definition of the Quaternary with its base at ~2.6 Ma to encompass the time interval during which (1) the Earth's climate has been strongly influenced by bipolar glaciation and (2) the genus *Homo* first appeared and evolved (Pillans and Naish, 2004). Figure 2 summarizes the major temporal and latitudinal relations between orbital forcing and the Earth's late Pliocene–early Pleistocene climate (3.0–1.5 Ma) as accounted in various records, including high-resolution deep ocean $\delta^{18}\text{O}$ ice volume record from southwest Pacific ODP Site 1123, glacioeustatic cyclothems of Wanganui Basin New Zealand, ice rafting as recorded by magnetic susceptibility at North Pacific ODP Site 882, a median grain size profile from Jingchuan loess section in China, and a pollen summary diagram from ODP 658 (offshore West Africa) showing progressive aridification. A step-like increase in African aridity at about 2.8 Ma is linked to a significant event in hominid evolution in East Africa as the genera *Paranthropus* and *Homo* emerge from a single lineage (Pillans and Naish, 2004).

Figure 1 The evolving chronostratigraphic subdivision of the Cenozoic according to recent and proposed iterations of the international geological time scale (GTS). Sources: GTS1982 (Harland et al., 1982), GTS1989 (Harland et al., 1990), GTS2004 (Gradstein et al., 2004) and GTS2012 (Gradstein et al., 2012). For simplicity, stages of pre-Pliocene Series are not shown.

In August 2005, a joint ICS-INQUA Task Group, which had been established to resolve the issue of how best to define the Quaternary, made the following recommendations:

1. The Quaternary should be recognized as a formal chronostratigraphic/geochronologic unit.
2. The lower boundary of the Quaternary should coincide with the base of the Gelasian Stage (~2.6 Ma) and thus be defined by the Gelasian GSSP.
3. The Quaternary should have the rank of either System/Period above a shortened Neogene, or Sub-erathem/Sub-era within the Cenozoic and correlative with the upper part of an extended Neogene.

In September 2005, a meeting of the ICS recommended that the Quaternary be formally defined as a Sub-Era of the Cenozoic Era and that its base be defined by the GSSP for the Gelasian

Stage of the Upper Pliocene (see below). However, this proposal was rejected by INQUA, in favor of a Quaternary System/Period.

Finally, in June 2009, the Executive Committee of the International Union of Geological Sciences (IUGS) formally ratified a proposal by ICS to define the base of the Quaternary System at the GSSP for the Gelasian Stage at Monte San Nicola in Italy (Gibbard et al., 2010). At the same time, the base of the Pleistocene was also lowered to coincide with the Gelasian GSSP. Thus, the Gelasian Stage was transferred from the Pliocene Series to the Pleistocene Series (Figure 1).

The Gelasian Stage

The Gelasian Stage was originally defined as the youngest of three stages that make up the Pliocene Series. The GSSP for the Gelasian Stage is located in the Monte San Nicola section (Figure 3) near the town of Gela in Sicily (Rio et al., 1998). It is defined at the base of the marly layer overlying sapropel MPRS 250, an organic-rich horizon with an astronomically calibrated age of 2.588 Ma (Lourens et al., 1996, 2004). The Gauss/Matuyama paleomagnetic boundary occurs about 1 m (20 ka) below MPRS 250 and provides a close approximation for global correlation of the base of the Gelasian (=base of Quaternary System).

The Pleistocene Series

The GSSP for the Pliocene–Pleistocene boundary (=base Pleistocene) was originally located in the Vrica section, 4 km south

Figure 2 Summary of links between orbital forcing and paleoclimatic changes around 2.6 Ma that define the base of the Quaternary. Reproduced from Pillans B and Naish T (2004) Defining the Quaternary. *Quaternary Science Reviews* 23: 2271–2282.

Figure 4 Former GSSP (top of marker bed 'e') for the Pleistocene Series, Vrica section, southern Italy (Aguirre and Pasini, 1985), now the GSSP for the Calabrian Stage. Source: Web site of the International Commission on Stratigraphy, <http://www.stratigraphy.org/>.

of Crotona in Calabria, southern Italy (Figure 4). The boundary was defined at the top of a sapropel layer 'e' (Aguirre and Pasini, 1985) with an astronomically calibrated age of 1.806 Ma (Lourens et al., 1996, 2004). The boundary lies just above the top of the Olduvai Subchron, which facilitates global correlation. This GSSP has now been proposed as the base of the Calabrian Stage (Cita et al., 2008).

Subdivision of the Pleistocene Series

Three working groups of the ICS are currently seeking suitable GSSPs to define the Upper, Middle, and Lower Pleistocene.

Lower Pleistocene

By definition, the GSSP for the Lower Pleistocene should be the base Pleistocene GSSP at Monte San Nicola section in Sicily. It is proposed that the Lower Pleistocene Subseries will comprise the Gelasian and Calabrian Stages.

Middle Pleistocene

Participants in the Burg Wartenstein Symposium 'Stratigraphy and Patterns of Cultural Change in the middle Pleistocene,' held in Austria in 1973, recommended that the beginning of the middle Pleistocene be defined to either coincide with, or be linked to, the Matuyama–Brunhes paleomagnetic reversal boundary (Butzer and Isaac, 1975). A similar recommendation

was made by the INQUA Working Group on Major Subdivision of the Pleistocene at the XIIth INQUA Congress in Ottawa in 1987 (Richmond, 1996), and although potential GSSPs in Japan, Italy, and New Zealand were discussed, no decision was reached. Pillans (2003) also advocated the Matuyama–Brunhes boundary (MBB), because it constitutes the most recognizable chronostratigraphic marker in weathered continental deposits.

At present, the SQS Working Group on the Lower–middle Pleistocene Boundary is considering candidate sections in Italy and Japan, having resolved at the 32nd International Geological Congress in Florence in 2004 to place the boundary as close as possible to the MBB.

Upper Pleistocene

The Middle–Upper Pleistocene boundary is generally placed at the beginning of the Last (Eemian) Interglacial or at the beginning of Marine Isotope Stage 5 (MIS 5), with an age of ~130 000 years (Gibbard, 2003). However, detailed pollen analyses of marine cores to the west of Portugal have shown that the base of MIS 5 is significantly older (~60 000 years) than the base of the Eemian (Shackleton et al., 2003; Figure 5).

Figure 5 Marine and continental records of the last (Eemian) interglacial compared with MIS 5e in marine core MD95-2024. Reproduced from Shackleton NJ, Sanchez-Goni MF, Paillet D, and Lancelot Y (2003) Marine Isotope Substage 5e and the Eemian Interglacial. *Global and Planetary Change* 36: 151–155.

Gibbard (2003) has argued that the Upper Pleistocene GSSP should be chosen in a high-resolution terrestrial sequence at the base of the Eemian, and he nominates a depth of 63.5 m in the Amsterdam Terminal borehole as a candidate GSSP.

Holocene Series

For many years, the base of the Holocene Series (= top of Upper Pleistocene) was broadly accepted as the end of the last glacial period, with an age of 10 000 radiocarbon years. However, this definition was never ratified by ICS. In 2008, the GSSP was formally defined at a depth of 1492.3 m in the NGRIP ice core from Greenland, reflecting the first signs of climatic warming at the end of the Younger Dryas (Walker et al., 2008, 2009). The age of the boundary, based on multi-parameter annual layer counting is 11 734 cal ¹⁴C years BP. This GSSP is the first to be defined in an ice core.

Local Chronostratigraphic Units and Time Scales

In most regions of the world, fossils remain the principal means of establishing the age and sequence of Phanerozoic rocks, including many Quaternary deposits. However, while it is generally possible, using biostratigraphy to correlate deposits with the major chronostratigraphic units of the GTS at Series level and above, regional endemism of biota often makes correlation at finer scales (e.g., Stage level) problematic. Establishment of local time scales is a solution to this problem.

Numerous local 'time scales' have been erected for regional subdivision of the Quaternary, but the majority of these are, strictly speaking, climatostratigraphic units, not chronostratigraphic units. Furthermore, few of the regional stages have been formally defined using Local boundary Stratotype Sections and Points (LSSPs). A notable exception is in New Zealand, where most Cenozoic local stages are defined (or are in the process of being defined) by LSSPs in marine sequences. These include the New Zealand Haweran, Castlecliffian, and Nukumaruan Stages with LSSPs in Wanganui Basin (Cooper, 2004).

The need for local time scales is increasingly debated. However, in relatively isolated regions such as New Zealand, so long as fossils remain the principal means of correlation, it seems likely that local time scales will be required.

Chronostratigraphic Markers

A chronostratigraphic horizon or marker is a stratigraphic surface that is everywhere of the same age (Salvador, 1994). Although they are theoretically without thickness, in practice, the term chronostratigraphic horizon (or chronohorizon) has been applied to very thin and distinctive markers that are essentially the same age over their whole geographic extent. Examples of chronostratigraphic markers in the Quaternary include tephras, magnetic polarity reversal horizons, and tektites. The latter are glassy objects produced from melted crustal rocks that are caused by large hypervelocity meteorite impacts. About 800 000 years ago, a large extraterrestrial impact occurred in southeast Asia, producing tektites, which are

Figure 6 Chronostratigraphic units, paleomagnetic datums and ages (from Lourens et al., 2004) for the Quaternary. Orbital variations in obliquity and eccentricity from Berger and Loutre (1991). Oxygen isotope record from ODP Site 607 from Raymo et al. (1989).

found over a wide area, including much of Australia and surrounding oceans – these are usually referred to as Australites or Australasian tektites. Zhou and Shackleton (1999) used the Australasian tektite layer to demonstrate the misleading position of the MBB in Chinese loess, concluding that there was a time delay in remanence acquisition in the loess and a downward displacement of the apparent position of the MBB. Such a study is a pertinent reminder that magnetic reversal boundaries are not everywhere isochronous.

Finer Subdivision of the Quaternary Using Marine Isotope Stages

Based on analysis of Foraminifera in deep-sea cores, oxygen isotope records, have been divided into marine isotope stages (MIS), numbered from the top downward (Figure 6). Because the $\delta^{18}\text{O}$ signal dominantly reflects changes in the oxygen isotopic composition of the global ocean, the stages have been used to provide a framework for global correlation of marine cores, limited only by the mixing time of the ocean and deep-sea sediment bioturbation rates. Indeed, as Shackleton and Opdyke (1973: 48) famously predicted: “Thus it is highly unlikely that any superior stratigraphic subdivision of the Pleistocene will ever emerge.”

MIS are numbered so that odd numbers correspond with $\delta^{18}\text{O}$ minima (interglacial stages) and even numbers correspond with $\delta^{18}\text{O}$ maxima (glacial stages). MIS 1 corresponds to the present interglacial period and stages are numbered sequentially down to MIS 103 at the base of the Quaternary (Figure 6), and beyond.

MIS boundaries are placed at points of maximum change between maxima and minima. However, additional events (maxima and minima) have been identified and numbered within many stages. Prell et al. (1986) introduced a numbering system for these events whereby, for individual isotopic events within any stage, the integer portion of the code represents the MIS number and the decimal number refers to the event. As in MIS nomenclature, even number decimals refer to $\delta^{18}\text{O}$ maxima and odd number decimals refer to $\delta^{18}\text{O}$ minima. Thus, event 5.5 is the lower interglacial event in MIS 5 corresponding to Stage 5e of Shackleton and Opdyke (1973). In the same way, upper MIS boundaries are assigned a zero decimal, so event 5.0 corresponds to the MIS 4/5 boundary.

Although not representing true chronostratigraphic horizons, MIS and isotopic events are widely used as such, particularly for correlation between deep-sea cores. Furthermore, they are frequently used for correlation between marine and terrestrial sequences, a practice that ignores the likely leads and lags between marine and terrestrial indicators of past environmental change (cf. the ~6000 year estimated offset between the pollen and isotopic records of MIS 5.5 recorded in cores off the coast of Portugal by Shackleton et al. (2003)).

Astronomical Timescale

Prior to 1950 and the development of modern radiometric dating techniques such as radiocarbon, Quaternary chronology was rather speculative. Early attempts to infer ages for various

glacial deposits using the chronology of orbital variations and resultant solar insolation curves (calculated by Milankovitch and others) were greeted with some skepticism. However, in the late 1960s and early 1970s, the astronomical chronology received strong support from dated coral reef sequences in New Guinea and Barbados (e.g., Broecker et al., 1968). However, it was Hays et al. (1976) who provided the first convincing evidence that the independent contributions of all the three orbital elements (obliquity, precession, and eccentricity) could be recognized in the geological record.

Today, the astronomical chronology of deep-sea cores is highly developed, and based on astronomical calibrations, the ages of all isotope stages and magnetic reversals in the Quaternary (and much of the Neogene) are well established (e.g., Lisiecki and Raymo, 2005; Lourens et al., 1996; Shackleton et al., 1990; see Figure 6). Astronomical calibration of marine sequences in the Mediterranean provides highly precise numerical ages for individual sedimentary cycles, including the Pleistocene and Gelasian (=Quaternary) GSSPs (Lourens et al., 2004). Astronomical calibration of the shallow marine sedimentary record from the Wanganui Basin in New Zealand has also been completed for the entire Quaternary (Naish et al., 1998, and updated by Pillans et al., 2005) and provides the primary chronology for LSSPs of the New Zealand Quaternary stages (Cooper, 2004).

Climatostratigraphy

P L Gibbard, University of Cambridge, Cambridge, UK

© 2013 Elsevier B.V. All rights reserved.

In contrast to the rest of the Phanerozoic, the Quaternary has a long-established tradition of sediment sequences being divided on the basis of represented climatic changes, particularly sequences based on glacial deposits in central Europe and mid-latitude North America. This approach was adopted by early workers for terrestrial sequences because it seemed logical to divide till (glacial diamicton) sheets and nonglacial deposits or in stratigraphical sequences into *glacial* (glaciation) and *interglacial* periods, respectively (cf. West, 1977; Bowen, 1978; West, 1984). In other words, the divisions were fundamentally lithological (Figure 1). The overriding influence of climatic change on sedimentation and erosion in the Quaternary has meant that, despite the enormous advances in knowledge during the last century and a half, climate-based classification has remained central to the subdivision of the succession. Indeed, the subdivision of the modern ocean-sediment isotope stage sequence is itself based on the same basic concept. It is this approach that has brought Quaternary geology so far, but at the same time has caused considerable confusion to workers attempting to correlate sequences from enormously differing geographical and thus environmental settings. This is because of the great complexity of climatic change and the very variable effects of the changes on natural systems.

The recognition of climatic events from sediments is an inferential method and by no means straightforward. Sediments are not unambiguous indicators of contemporaneous climate, so that other evidence such as fossil assemblages, characteristic sedimentary structures (including periglacial structures) or textures, soil development, and so on must be relied upon wherever possible to illuminate the origin and climatic affinities of a particular unit. Local and regional variability of climate complicates this approach in that sequences are the result of local climatic conditions, yet there remains the need to equate them to a global scale. For at least the first half of the twentieth century, the preferred scale was that developed for the Alpine region at the turn of the century by Penck and Brückner (1909) (Figure 2).

Since the mid-twentieth century, a comparable scheme developed in northern Europe has been dominant, at least in Europe, but similar schemes were established elsewhere, such as North America, or the former USSR (Table 1). More recently, these schemes have tended to be replaced by the marine or ice-core oxygen isotope records (see *Oxygen-Isotope Stratigraphy of the Oceans; Correlations Between Greenland and Antarctica*). Today the burden of correlation lies in equating local, highly fragmentary, yet high-resolution terrestrial and shallow marine sediments on the one hand, with the potentially continuous, yet comparatively lower resolution ocean-isotope sequence on the other (cf. Gibbard and van Kolfschoten, 2005).

Terminology

Before the impact of the ocean-core isotope sequences, an attempt was made to formalize the climate-based stratigraphical

terminology in the American Code of Stratigraphic Nomenclature (1961) where so-called geologic-climate units were proposed. Here a geologic-climate unit is based on an inferred widespread climatic episode defined from a subdivision of Quaternary rocks (American Code, 1961). Several synonyms for this category of units have been suggested, the most recent being climatostratigraphical units (Mangerud et al., 1974) in which a hierarchy of terms is proposed. In subsequent, stratigraphic codes, however (Hedberg, 1976; North American Commission on Stratigraphic Nomenclature, 1983; Salvador, 1994), the climatostratigraphic approach has been discontinued since it was considered that for most of the geological column 'inferences regarding climate are subjective and too tenuous a basis for the definition of formal geologic units' (North American Commission, 1983: p 849). This view does not find favor with Quaternary scientists, however, since it is difficult to envisage a scheme of stratigraphic subdivision for recent earth history that does not specifically acknowledge the climate-change factor (Lowe and Walker, 1997). Accordingly, Quaternary stratigraphical sequences continue to be divided into geologic-climatic units based on proxy climatic indicators, and hence following with this approach, the Pleistocene–Holocene boundary (the base of the Holocene Series/Epoch) for example, is defined on the basis of the inferred climatic record. Boundaries between geologic-climate units were to be placed at those of the stratigraphic units on which they were based.

The American Code (1961) defines the fundamental units of the geologic-climate classification as follows:

A *glaciation* is a climatic episode during which extensive glaciers developed, attained a maximum extent, and receded. A *stadial* ('stade') is a climatic episode, representing a subdivision of a glaciation, during which a secondary advance of glaciers took place. An *interstadial* ('interstade') is a climatic episode within a glaciation during which a secondary recession or standstill of glaciers took place.

An *interglacial* ('interglaciation') is an episode during which the climate was incompatible with the wide extent of glaciers that characterize a glaciation.

In Europe, following the work of Jessen and Milthers (1928), it is customary to use the terms *interglacial* and *interstadial* to define characteristic types of nonglacial climatic conditions indicated by vegetational changes; *interglacial* to describe a temperate period with a climatic optimum at least as warm as the present interglacial (Holocene, Flandrian: see below) in the same region, and *interstadial* to describe a period that was either too short or too cold to allow the development of temperate deciduous forest or the equivalent of interglacial-type in the same region (West, 1977).

In North America, mainly in the United States, the term *interglaciation* is occasionally used for interglacial (cf. American Code, 1961). Likewise, the terms *stade* and *interstade* may be used instead of *stadial* and *interstadial*, respectively (cf. American Code, 1961). The origin of these terms is not certain but the latter almost certainly derive from the French language word *stade* (m), which is unfortunate since in French *stade*

Figure 1 Fossiliferous sand deposits between tills exposed in the Cowden Burn railway cutting at Neilston in Renfrewshire, Scotland. Reproduced from Geikie J (1874) *The great Ice Age and Its Relation to the Antiquity of Man*. London: W. Isbister, Figure 27.

means (chronostratigraphical) stage (cf. Michel et al., 1997), for example, *stade isotopique marin* = marine isotope stage.

It will be readily apparent that, although in longstanding usage, the glacially based terms are very difficult to apply outside glaciated regions. Moreover, Suggate and West (1969) recognized, the term Glaciation or Glacial is particularly inappropriate since modern knowledge indicates that cold rather than glacial climates have tended to characterize the periods intervening between interglacial events over most of the earth. They therefore proposed that the term 'cold' stage (chronostratigraphy) be adopted for 'glacial' or 'glaciation.' Likewise, they proposed the use of the term 'warm' or 'temperate' stage for interglacial, both being based on regional stratotypes. Lüttig (1965) also recognized this problem and attempted to avoid the glacial connotations by proposing the terms *cryomer* and *thermomer* for cold and warm periods, respectively. These terms have found little acceptance, however. The local nature of these definitions indicates that they cannot necessarily be used across great distances or between different climatic provinces (Suggate, 1974; Suggate and West, 1969; West, 1977) or indeed across the terrestrial/marine facies boundary. In addition, it is worth noting that the subdivision into glacial and interglacial is mainly applied to the Middle and late Pleistocene.

Boundaries

Perhaps the biggest problem with climate-based nomenclature is where the boundaries should be drawn. Ideally they should be placed at the climate change, but since the events are only recognized through the responses they initiate in depositional or biological systems, a compromise must be agreed. As Bowen (1978) emphasizes, there are many places where boundaries could be drawn, but in principle they are generally placed at mid-points between temperature maxima and minima, for example, in ocean-sediment sequences. This positioning is arbitrary but is necessary because of the complexity of climatic changes. However, problems may arise when attempts are made to determine the chronological relationship of boundaries drawn in sequences of differing temporal resolution or sediment facies, and indeed determined using differing proxies. By contrast in temperate Northwest Europe the base of an interglacial or interstadial (see Overview) is very precisely defined. It is placed at the point where herb-dominated (cold-climate) vegetation is replaced by forest. The top (i.e., the base of the subsequent glaciation or cold stage) is drawn where the reverse occurs (Jessen and Milthers, 1928; Turner and West, 1968). It is unclear, however, how this relates to the timing of the actual climate change recorded or how the change is recorded by other proxies.

Climatostratigraphic Units are not Chronostratigraphic Units

In the second half of the twentieth century, it was a recognized that Quaternary time should be subdivided as far as possible in keeping with the rest of the geological column using time, or chronostratigraphy, as the basic criterion (e.g., Gibbard and West, 2000; van der Vlerk 1959). Because stages are the fundamental working units in chronostratigraphy (see Chapter Chronostratigraphy), they are considered appropriate in scope and rank for practical intraregional classification (Hedberg, 1976). However, the definition of stage-status chronostratigraphical units, with their time-parallel boundaries placed in continuous successions wherever possible, is a serious challenge especially in terrestrial Quaternary climate-dominated sequences. In these situations, boundaries in a region may be time-parallel but over greater distances problems may arise as a result of diachroneity. It is probably correct to say that only in continuous sequences that span entire interglacial–glacial–interglacial climatic cycles can an unequivocal basis for the establishment of stage events using climatic criteria be truly successfully achieved. There are the additional problems that accompany such a definition of a stage, including the question of diachroneity of climate changes and the detectable responses to those changes. For example, it is well known that there are various 'lag'-times of physical or biological responses to climatic stimuli. Thus, in short, climate-based units cannot be the direct equivalents of chronostratigraphical units because of the time-transgressive nature of former. This distinction of a stage in a terrestrial sequence from that in a marine sequence should be remembered.

In general practice today, the climatic subdivisions have been used interchangeably with chronostratigraphical stages by the majority of workers. While this approach, which gives rise to alternating 'cold' and 'warm' or 'temperate' event-based stages, has been advocated for 40 years, there remains considerable confusion about the precise distinction between the schemes, particularly among the non-geological community, that is working on Quaternary sequences. In Europe, many of the terms in current use, perhaps surprisingly, do not have defined boundary- or unit-stratotypes. This problem has been recognized and steps are now being taken to define units formally through the work of the INQUA Subcommission (Section) on European Quaternary Stratigraphy. However, many fail to see the need for this, especially those who rely on geochronology, particularly radiocarbon (see Conventional Method), for correlation. For example, despite repeated attempts to propose a Global Stratotype Section and Point boundary stratotype for the base of the Holocene Series, Pleistocene–Holocene (Weichselian–Flandrian) boundary (Olausson, 1982) in the past, only recently has a universally

Figure 2 Sketch longitudinal sections through the gravel district of the northern Alpine Foreland of southern Germany showing the distribution of glaciofluvial sediments and their relationship to end-moraines of alpine glaciations by Albrecht Penck. These units are those upon which the original Alpine glacial classification was based. Reproduced from Penck A and Brückner E (1909) *Die Alpen im Eiszeitalter. Glacial	Günz		Nebraskan	?

acceptable boundary been defined (Walker et al., 2008). Subdivision of the Holocene is likely to rely on geochronology for the foreseeable future.

In addition to the formal definition of local sequences, the Pleistocene is now being subdivided into a series of 'standard stages,' comparable in scale to those defined for the preceding Neogene. The scheme, developed for marine sequences in Italy and summarized by Cita (2008), relies on the division of the sequence based on a range of parameters independent of climate. Advances in micropaleontology, paleomagnetic chronology and stable-isotope cyclostratigraphy in the upper Cenozoic marine strata of southern Italy have been used as a basis for the recognition of proposed Pleistocene global chronostratigraphical units in the same situation as the Quaternary/Pleistocene boundary stratotype, independent of climatic oscillations. In this scheme the Pleistocene is divided into the: Gelasian, Calabrian, 'Ionian,' and 'Tarentian' stages. This scheme is in the process of being defined at the time of writing (Cita, 2008).

Nomenclatural Complexities

In languages other than English, the situation is more confused. For example, in German, the terms *Glazial* and *Interglazial* (also '*Kaltzeit*' and '*Warmzeit*,' respectively) are used as equivalents of the English-language stage. Such an approach, on the face of it, seems expedient until one considers certain stages that have been correctly, formally defined in the Netherlands' Middle and early Pleistocene, which are commonly used throughout Europe. Here, for example, the Bavelian Stage includes two interglacial and two glacial events, likewise the Tiglian Stage comprises at least three interglacials and two glacials, and the Cromerian Complex Stage includes four interglacial and three glacial events (de Jong, 1988; Zagwijn, 1992). Each of these interglacials is comparable in their characteristics to the last interglacial or Eemian which is a discrete stage, also defined in the Netherlands. This problem of conflicting status has led workers to adopt the noncommittal term *complex* to group events. One example is the Saalian of Germany – originally defined as a glaciation, this chronostratigraphical stage includes at least one interglacial, as currently defined (Litt and Turner, 1993). This attempt to circumvent the nomenclatural problem by defining a 'Saalian Complex' is a

fudge at best but one that is occasioned by linguistic and long-term historical precedent, as much as by geological needs.

Global Correlation

The original intention was that 'cold' or 'warm' or 'temperate' stages should represent the first-rank climate oscillations recognized, an approach that originates from the earliest classification of ice-age events (e.g., Geikie, 1874). However, it has since been realized that some, if not all the events, are themselves internally complex. Subdivision of these stages into substages or zones was to be based, in the case of temperate stages, on biostratigraphy, and in the case of cold stages principally on lithostratigraphy and or pedostratigraphy. Within the range of radiocarbon dating (ca. 30 ka), the most satisfactory form of subdivision is frequently that based on radiocarbon years (cf. Shotton and West, 1969). However, high-resolution investigations, such as the ice-core investigations (see *Stable Isotopes, Correlations Between Greenland and Antarctica*) have allowed the recognition of ever more climatic oscillations of decreasing intensity or wavelength within the first-rank time divisions. These events are stretching the ability of the stratigraphical terminology to cope with the escalating numbers of names they generate. Terms such as 'event,' 'oscillation,' or 'phase' are currently in use to refer to short or small-scale climatic events (often referred to as 'sub-Milankovitch oscillations': see *Sub-Milankovitch (DO/Heinrich) Events*). Clear hierarchical patterns are becoming blurred but perhaps this should be seen as a positive development since the system must reflect the need to classify events that are recognized. Moreover, as our ability to resolve smaller and smaller scale oscillations increases, a more detailed nomenclature will inevitably emerge. One possible approach is to avoid attempted chronostratigraphical classification in favor of an event-scheme based on the recognition of 'diachronic units' (e.g., Curry et al., 2011) but in reality this differs little from that based on climate.

Therefore, for many Quaternary workers, chrono- and climatostratigraphical terminology remain interchangeable. Although this situation is clearly unsatisfactory, because of the imprecision that it may bring to interregional and ultimately to global correlation, realistically it is likely to continue for the foreseeable future. The long-term goal should be to clarify the situation by continuing to develop a formally

defined, chronostratigraphically based system that is fully compatible with the rest of the geological column, supported by reliable geochronology.

Lithostratigraphy

W E Westerhoff, Geological Survey of the Netherlands - TNO, Utrecht, The Netherlands

H J T Weerts, Cultural Heritage Agency, Amersfoort, The Netherlands

© 2013 Elsevier B.V. All rights reserved.

Introduction

Ever since Earth scientists have started to study the Earth they have all attempted to describe and classify what they saw and communicate their observations. Since observations in Earth science deal with the properties of strata on top of each other (in outcrops or in drillholes), these communications dealt with stratigraphy; that is, the description of the layers that were observed. Layers of rock can be described in many ways, and so it happened, and still happens. Depending on the background of the Earth scientist, description and classification was at first based on fossil content (biostratigraphy) and/or lithology (lithostratigraphy). This was especially so in the eighteenth and nineteenth century. Advances in chemistry and physics in the twentieth century enabled other methods of classification of rocks (e.g., chemo-, chrono-, magneto-, and seismostratigraphic). Although this was a clear advance in geosciences, it soon appeared that it also obscured clear communication. Fortunately, this was broadly understood and in 1976, the first edition of the International Stratigraphic Guide was published (Hedberg, 1976). This publication showed the way to clarification of concepts. Advancing knowledge in stratigraphy led to a second edition in 1994 (Salvador, 1994). This edition incorporated developments and concepts that were not included in the first edition. Recent publications by Walsh (2005a,b,c) point out the need for further clarification. This article is based on the principles of lithostratigraphic classification as defined by Hedberg (1976) and Salvador (1994) and the modifications proposed by Walsh (2005a). It is further based on the application of these principles on Quaternary deposits and on recent experiences in Northwestern Europe (Bowen, 1999a,b; Ebbing et al., 2003; Gullentops et al., 2001; Kemna and Westerhoff, 2007; McMillan, 2002, 2005; Rijdsdijk et al., 2005; Weerts et al., 2005; Westerhoff, 2009; Westerhoff et al., 2003).

Lithostratigraphic Classification

What Is Lithostratigraphy?

There are as many definitions of lithostratigraphy as there are textbooks. In short, lithostratigraphy is the classification of bodies of rock based on the observable lithologic properties of the strata and their relative stratigraphic positions (after Hedberg, 1976; Nichols, 1999; Salvador, 1994). This implies that observable lithologic properties and stratigraphic position are the only criteria to be used when defining lithostratigraphic units. In the Quaternary record, the 'rock' is often not lithified. In many definitions of lithostratigraphy, the concept of the study of outcrops is explicitly or implicitly present. Outcrops of Quaternary deposits are scarce and often short-lived. Furthermore, Quaternary deposits are absent or very thin in large

parts of the world. Thickness, however, is no criterion in defining lithostratigraphic units (Hedberg, 1976; Salvador, 1994). Apart from that, the description of rock units or deposits encountered in drillholes can replace observations at outcrops. So, the general lithostratigraphic concepts can be applied to the Quaternary sedimentary record for surficial as well as subsurface reconnaissance just as they do to older deposits.

There is common agreement on mapability as the key criterion for the validity of a lithostratigraphic unit (Bowen, 1983; Brookfield, 2004; Cox and Sumbler, 1998; Hedberg, 1976; Krumbein and Sloss, 1963; Nichols, 1999; Salvador, 1994). Typically, lithostratigraphic units are defined for and used in detailed geologic mapping (scale of about 1:25 000). In fact a new formation needs to be tested on its mapability. Therefore, a lithostratigraphic unit that cannot be mapped makes no sense. Before proceeding into definitions and considerations, we should remember that, just like any other stratigraphic classification, lithostratigraphy is only a tool! It is not a goal in itself. Its purpose is communication, interpretation, and correlation. To be able to do so we need (i) clear definitions, and (ii) clear rules of application.

There are of course several stratigraphic methods (lithostratigraphy, biostratigraphy, chronostratigraphy, sequence stratigraphy, and so on). Figure 1 shows a simplified outcrop that is classified in various ways. Note that the boundaries between the several stratigraphic units sometimes coincide but just as often they do not. One should always make clear which type of stratigraphic method and unit one uses and one should apply the definitions and rules of application of that particular type properly. This may seem tedious (and in fact it often is) but it is absolutely necessary to avoid confusion.

Following Hedberg (1976), Salvador (1994), and Walsh (2005a), a lithostratigraphic scheme: (i) has a hierarchic structure with the formation as the central unit, (ii) has a clear nomenclature, (iii) describes each unit properly, and (iiii) contains mapable units only.

Hierarchic Structure

Every rock unit has to be assigned to a formation. A formation may be divided into several members and beds, but this is not compulsory. A bed can be placed directly within a formation or within a member. Formations may be grouped into subgroups, groups, and supergroups but this is also not compulsory. At the subgroup level and higher, the lithostratigraphic units are based on interpretation rather than on observation. These higher hierarchy units consist of lower hierarchy units identifiable by observations (in core descriptions or in outcrops) that are grouped together by interpretation that usually is based on some kind of conceptual model. In our approach, lithostratigraphic units typically range from architectural element assemblages to basin fills (Figure 2).

Figure 1 A hypothetical outcrop classified by several stratigraphic methods. Modified from Salvador A (ed.) (1994) *International Stratigraphic Guide: A Guide to Stratigraphic Classification, Terminology, and Procedure*. *International Subcommission on Stratigraphic Classification of IUGS International Commission on Stratigraphy*, 2nd edn., 214 p. Trondheim: International Union of Geological Sciences; Boulder, CO: Geological Society of America.

A formation in our sense is regarded as an architectural element assemblage (cf. Miall, 1985) and is therefore nearly always lithologic heterogeneous. Although this may sound strange, it is completely in line with the international guidelines. “The degree of change in lithology required to justify the establishment of distinct formations [...] is not amenable to strict and uniform rules. It may vary with the complexity of the geology of a region and the detail needed to portray satisfactorily its rock framework and to work out its geologic history” (Salvador, 1994, p. 33). Formations usually consist of a network of architectural elements (Miall, 1985, 1996) that are confined to a certain stratigraphic level. Because of the mapability criterion, we strongly discourage the widespread habit of assigning formal member or bed status to individual architectural elements or facies units. It is perfectly sound to identify these units within a formation without that formal status (Figure 3). Assigning formal lithostratigraphic status to them will in many cases lead to unjustifiable correlations. Indeed, there are numerous examples where this has happened. With respect to this, one should bear in mind that lithostratigraphy is not synonymous with lithology.

The definition of a member in our sense slightly differs from that of Salvador (1994). We propose to define a member as a named entity within the formation when it possesses lithologic properties distinguishing it from adjacent parts of the formation and/or it is present at a distinct stratigraphic level within the formation.

A bed in our view is used only to identify a well recognizable stratum (strata) that acts as a regional marker. Consequently, we advise limited use of the bed. A bed is typically less than 2 m thick. It should be noted that we deviate from the guidelines of Hedberg (1976) and Salvador (1994) here.

Rules of Application and Nomenclature

Defining a lithostratigraphic unit

Reading the nomenclatural regulations of any branch of science usually makes scientists yawn. Yet, it is an aspect of science that deserves our attention. In that light the publications of Walsh (2005a,b,c) provide interesting reading for Earth scientists dealing with stratigraphy. Although his papers mainly deal with bio- and chronostratigraphy, his observations are valid in lithostratigraphy as well. We use many of his views here.

Every lithostratigraphic unit should be properly defined and named. Hedberg (1976) and Salvador (1994) provide nomenclatural rules. Each unit should have a name that consists of two parts: the name of the unit (*nominal* part) and the rank of the unit (*hierarchical* part). The name should be derived from the location where the unit is defined, based on a drill-hole or an outcrop at that location. The drillhole or outcrop serves as its *stratotype*. A stratotype should be accessible for other researchers. In the Quaternary record, drillholes usually serve as stratotypes. Because the deposits themselves cannot be

Figure 2 Lithostratigraphy and scale. Lithostratigraphic units typically range from architectural elements and sequences to basin fills. Adapted from Heinz J and Aigner Th (2003) Hierarchical dynamic stratigraphy in various Quaternary gravel deposits, Rhine glacier area (SW Germany): Implications for hydrostratigraphy. *International Journal of Earth Sciences* 92: 923–938.

observed at the stratotype location, authors should provide an adequate description of the deposits in the drillhole along with the exact location of the drillhole.

Let us now assume that we have an excellent drillhole near the Eem river in the Netherlands (Figure 4(a) and 4(b)). At a certain level in that drillhole, marine deposits are present. These deposits can be recognized in the descriptions of the drillholes that are present in the database of the Geological Survey of the Netherlands. The deposits can be mapped over a large area and Lorié (1906) already described them. Zonneveld (1959, p. 54) presents a map of the deposits, compiled from work by Bennema and Pons (1952) and Van der Heide (1957). He calls the deposits 'Eem beds' (Dutch: Eemlagen; Zonneveld, 1959, pp. 56–58) but does not introduce them as a lithostratigraphic unit. This was done by Zagwijn (1961). Because he uses a series of drillholes near the Eem river to define the unit, the name of the unit is 'Eem.' Assigning a rank to a unit is always more or less arbitrary. We know that the Eem unit consists of siliciclastic marine deposits that can be easily recognized from core descriptions (based on their marine mollusks) and that the unit has a widespread occurrence at a

certain stratigraphic level. The lithologic properties of the unit strongly differ from the bounding units. Thus, when the unit was first introduced by Zagwijn (1961, p. 20) it was defined as a formation; the Eem Formation. Unfortunately, his definition was based on mixture of litho- and biostratigraphic criteria. He includes organic deposits 'related' to the marine deposits in the Eem Formation because of their (palynological inferred!) age. It also lacks a clear stratotype. A formal stratotype was defined in the formal definition of the Eem Formation by Doppert et al. (1975, pp. 48–49; summarized in Van Staalduinen et al., 1979, pp. 42–43). The excellent drillhole 32B0119 of the Geological Survey of the Netherlands serves as the original (holo)stratotype in their definition (Figure 4(a)). Apart from the marine deposits described above they also assign related organic deposits to the Eem Formation.

Nomenclatural rules

Once a lithostratigraphic unit has been defined, changes in its status should be documented properly. From mapping a given unit, it might, for instance, appear that the original stratotype only describes a part of the deposits of that unit. In that case,

Figure 3 Relationships between the boundaries of lithostratigraphic units (defined by lithological characteristics resulting from the depositional environment) and timelines in a succession of strata formed during gradual sea-level rise (modified from Nichols G (1999) *Sedimentology and Stratigraphy*, p. 238. Oxford: Blackwell Science). Note that the facies units cross timelines; age is no criterion in a lithostratigraphic classification. Also note the displacement of the depositional environment when sea level rises. The continental deposits (peat) form formation A; the coastal plain (predominantly clay), beach and dune (sand), and the shoreface deposits (sand) form formation B; the offshore deposits (sand) form formation C. The three sandy environments (i.e., beach and dunes, shoreface, and offshore) can be distinguished by their different lithologic properties (sand median, sedimentary structure, specific mollusk content).

one or more stratotypes should be added. Sometimes, the original stratotype even has to be replaced by a new one. Hedberg (1976) and Salvador (1994) give nomenclatural rules, which are summarized in Table 1. The original stratotype of a lithostratigraphic unit is by definition its holostatotype. The original author might add one or more parastratotypes if (s)he deems this necessary. Modifications defined afterwards lead to the definition of lecto-, neo-, or hypostatotypes. These rules must be obeyed to be able to always exactly know the status of a given stratotype. When looked at in detail, it appears that Hedberg's and Salvador's nomenclature only reveals the historic status of the stratotype. Walsh (2005a, pp. 320–323) therefore proposes another nomenclatural classification for stratigraphic units. He introduces three formal classes of stratotypes: (i) nominal, (ii) exemplary, and (iii) boundary-defining

stratotypes (Table 2). Walsh's (2005a) classification scheme defines the function of the stratotypes. We propose to use both Hedberg's/Salvador's nomenclatural rules and Walsh's rules for stratotype definition. This means that every stratotype has to be given both a status and a function. Walsh's (2005a,b,c) papers are mainly concerned with bio- and chronostratigraphy. In those fields, boundary-defining stratotypes are important. The nature of the unit boundaries changes over space. Therefore, the practical utility of boundary-defining stratotypes in lithostratigraphy is very limited. In lithostratigraphy, the nominal and exemplary functions of the stratotypes are of main importance. Caution should be taken in defining exemplary stratotypes too strictly as this leads to very rigid interpretations. We prefer to use loose exemplary stratotypes to describe the deposits of a given unit. If perception of a certain lithostratigraphic unit changes, its

Figure 4 Application of the nomenclatural rules to the Eem Formation, the Netherlands. (a) Simplified map of the occurrence of the Eem Formation including the location of the stratotypes. (b) Original stratotype of the Eem Formation (drillhole 32B0119), now obsolete. (c) New stratotype of the Eem Formation (drillhole 25E0913). See text for further explanation.

Table 1 Stratotype nomenclature, status

<i>Stratotype name</i>	<i>Stratotype status</i>
Holostratotype	The original stratotype designated by the original author at the time of proposing the stratigraphic unit
Lectostratotype	A stratotype for a previously defined stratigraphic unit selected later in the absence of an adequately defined original stratotype (defining lectostratotype) or A changed interpretation of the original holostratotype (changing lectostratotype) or A new stratotype that gives a more adequate description of the stratigraphic unit than its obsolete holostratotype (replacing lectostratotype)
Neostratotype	A new stratotype selected to replace an older one which has been destroyed or otherwise made inaccessible
Parastratotype	An additional stratotype used in the original definition by the original author to illustrate the diversity and/or heterogeneity of the stratigraphic unit or some critical feature that is not evident or exposed in the holostratotype
Hypostratotype	A stratotype proposed after the original definition of the holostratotype (and parastratotypes) in order to extend the knowledge of the unit to other geographic areas where it was not recognized earlier (extending hypostratotype) or A stratotype that expresses regional differences of the unit that were not defined by the original author (regional hypostratotype)

Note that we extended the original meaning of the lecto- and the parastratotype.

When using those status stratotypes, authors should indicate the *exact* status.

(1994) *International Stratigraphic Guide: A Guide to Stratigraphic Classification, Terminology, and Procedure. International Subcommission on Stratigraphic Classification of IUGS International Commission on Stratigraphy*, 2nd edn., 214 p. Trondheim: International Union of Geological Sciences; Boulder, CO: Geological Society of America.

hierarchical rank might also change. It is perfectly sound to 'demote' or 'promote' a formation to a member or (sub)group, as long as the arguments are published and the previous rank of the newly defined unit is described in its history. In the 'demotion' case, the original holostratotype of the demoted unit will probably serve as an exemplary regional hypostratotype of the new 'mother' unit. Finally, it might appear that a certain lithostratigraphic unit is not valid. In that case, the unit should be abandoned. 'Its' deposits should be incorporated in one or more existing or newly defined units. In both cases, this should be included in the definition of these units.

Let us now return to our Eem Formation example. We have to assign one or more functions to the holostratotype (Table 3). As the name of the Eem Formation is derived from the river Eem that flows near the location of drillhole 32B0119, it is a nominal stratotype. The drillhole gives an example of Eem Formation deposits, so it is also an exemplary stratotype.

Table 2 Functional stratotype nomenclature. See text for further details

Exemplary stratotype	A specific stratigraphic section used to serve as a concrete example of an author's concept of one or more attributes of a particular stratigraphic unit
Nominal stratotype	A specific stratigraphic section that serves as the name bearer of a particular stratigraphic unit
Strict stratotype	All of the stratotype must always be included in the concept denoted by the name of the stratigraphic unit which it bears
Loose stratotype	At least some part of the stratotype must always be included in the concept denoted by the name of the stratigraphic unit which it bears
Boundary-defining stratotype	A specific stratigraphic section in which one or two specified horizons are used to define one or both boundaries of a particular stratigraphic unit. Such boundary definitions may be permanent or subject to modification with new data
Unit stratotype	A specific, physically superposed stratigraphic section whose designated base and top are used to define both the base and the top of a particular stratigraphic unit, both being defined by permanent <i>golden spikes</i>
Boundary stratotype	A specific, physically superposed stratigraphic section in which one specified horizon is used to define the base or the top of a particular stratigraphic unit, being defined by a permanent <i>golden spike</i>

Part 1. Stratotype functions. *Earth-Science Reviews* 69: 307–332.

In the original definition also, the boundaries of the unit were defined, so it has a third function as well as it is a unit stratotype. Finally, drillhole 32B0119 also served as the stratotype of the Eemian stage in the Netherlands (Zagwijn, 1961). Walsh (2005c) discusses at length the 'age-based-on-formation' principle, based on considerations by Wood et al. (1941). Although scientifically correct as long as the correct nomenclature is used (in our case 'Eem Formation' for the lithostratigraphic unit and 'Eemian stage' for the chronostratigraphic unit), we consider this practice unfortunate. It easily leads to confusion and it should be discouraged when introducing new units. For nomenclatural stability's sake, it is hardly possible – and indeed undesirable – to change widely used existing 'age-based-on-formation' nomenclature. However, every stratigrapher should be aware of the possible confusion (we refer the readers to Lawson (1979) and Walsh (2005a,b,c) for further reading on this topic).

With the ongoing 1:50 000 mapping of the Netherlands, it became clear that the deposits in the 32B0119 drillhole only represented a small part of the facies present in the Eem Formation. Furthermore, the deposits in the stratotype 'represented' only a small part of the Eemian stage (e.g., Jelgersma and Breeuwer, 1975; Zagwijn, 1983; several 1:50 000 Geological Survey of the Netherlands map sheets and their explanatory annotations). This called for a new stratotype both for the Eem Formation and for the Eemian stage. In 1997, the

Table 3 Changing stratotypes of the Eem Formation

Author	Stratotype	Status	Function
Zagwijn (1961)	Not given. Three interpreted sections near the Eem river in his paper probably are meant to serve as stratotype	Not defined	Not defined, probably nominal, exemplary and unit
Doppert et al. (1975)	Drillhole 32B0119 near the Eem river, interval between 12.00 and 27.71 m below the surface	Holostratotype	Nominal, exemplary and unit
Bosch et al. (2003)	Drillhole 25E0913 at Amsterdam Terminal, interval between 28.10 and 63.50 m below the surface	Replacing lectostratotype	Loose exemplary
	Drillhole 32B0119 near the Eem river, interval between 13.21 and 27.71 m below the surface	Changing lectostratotype	Nominal
Bosch et al. (2006)	Drillhole 25E0913 at Amsterdam Terminal, interval between 28.10 and 63.50 m below the surface	Replacing lectostratotype	Loose exemplary
	Drillhole 32B0119 near the Eem river, interval between 13.21 and 27.71 m below the surface	Changing lectostratotype	Nominal
	Drillhole P5-4 (P5-2 in Oele, 1971), interval between 2.75 and 6.0 m below the surface	Regional hypostratotype for the Eem Formation, holostratotype for the Brown Bank Member	Loose exemplary for the Eem Formation, nominal for the Brown Bank Member

Geological Survey of the Netherlands carried out a new drill-hole in Amsterdam from which undisturbed cores were taken in a former glacial basin that was formed during the Saalian glacial. The location was chosen because it was suitable for both chrono- and lithostratigraphic redefinition of the stratotype (De Gans et al., 2000). The 'Eemian' sediment units (sic!) in the drillhole were described in detail by Van Leeuwen et al. (2000, pp. 166–173). When the Eem Formation was redefined, Bosch et al. (2003) replaced the original holostratotype of the formation with this new drillhole (25E0913; Figure 3). Bosch et al. (2003) returned to the original concept of the Eem Formation. In their view, it only comprises the recognizable marine deposits at that particular stratigraphic level. The 'related' organic deposits are excluded from the formation. It had further appeared that a part of the deposits were fluvial reworked. The reworked marine deposits can be recognized based on their coarser lithology, often containing gravel (e.g., see Busschers et al., 2005; De Gans and De Groot, 1995; Törnqvist et al., 2000). They were also excluded from the formation. Both changes concern only a minor part of the original Eem Formation deposits. Finally, Bosch et al. (2003) included the former Brown Bank Formation as a member into the Eem Formation. The Brown Bank unit was recognized as a mapable unit of predominantly marine origin of early Weichselian age by Oele (1971) and Cameron et al. (1984, 1989). It occurs at the same stratigraphic level as the Eem Formation. Age, however, is no reason for assigning the deposits to another formation (Figure 4). (Note that this is a fine example of the confusion that often arises when the 'age-based-on-formation' principle is misunderstood!)

What are the nomenclatural consequences of all these changes? Should we rename the Eem Formation to Amsterdam Formation? No! Clearly, the original holostratotype is no longer valid because it only describes a small part of the formation. The *concept* of the formation, however, has not changed. So, the name Eem Formation is maintained. The original holostratotype is now a *changing lectostratotype*. It retains its function as *nominal* stratotype but has lost its other functions. Drillhole 25E0913 is the new *loose exemplary, replacing lectostratotype* (erroneously

Table 4a Requirements of a lithostratigraphic unit description

Unit property	Contents
Name	Name and rank of the unit Name and rank of next higher hierarchic unit <i>Derivatio nominis</i>
Description of the lithologic properties	Lithology (general, dominant, subordinate, sporadic) Nature of the boundaries (lower and upper) Other characteristic features Regional differential lithologic properties, including short descriptions of potential units of lower rank that form part of the unit Thickness (minimal, maximal, average)
Stratotypes	Status and function stratotypes cf. Tables 2 and 3, including exact intervals in drillholes and/or sections Geographic coordinates, including a small detailed map of the stratotype area Description of the drillhole(s) or section(s), exactly indicating the unit interval Indicative map of the areal extent of the unit
Genesis	Description of the depositional environment(s), as far as relevant for the unit's lithologic properties
Relation to other (litho)stratigraphic units	Indication of possible confusion with other units due to lithologic similarities and/or intercalation
Relation to earlier described and defined units	Name of the older unit(s) that is (are) replaced by this one, if relevant Original publication where the present unit was defined, if relevant
Age	As precisely as possible, either chronostratigraphic or absolute
References	References deemed necessary for understanding the nature and properties of the unit

classified as parastratotype by Bosch et al., 2003). Although it may have boundary-defining use in chronostratigraphy, it is not defined as such in lithostratigraphy. Drillhole P5-4 (P5-2 in

Oele, 1971) serves as the *nominal* and *loose exemplary* stratotype for the Brown Bank Member and as a *regional hypostatotype* for the Eem Formation (Bosch et al., 2006).

Description of a Unit

A formal lithostratigraphic unit should be properly described. The description should contain its lithologic properties,

stratigraphic position, and (historic) nomenclature. It should also contain relevant information on its genesis, its (often presumed) age, its relation with other lithostratigraphic units. The latter is of extreme importance for mapping and modeling purposes. Table 4a summarizes the requirements of an adequate description (derived from the British Geological Survey and the Geological Survey of the Netherlands). Table 4b summarizes the description of the Eem Formation.

Table 4b Short description of the Eem Formation as example

<i>Eem formation</i>	
Name	<i>Unit:</i> Eem Formation <i>Mother unit:</i> Upper North Sea Group cf. Van Adrichem Boogaert & Kouwe (eds., 1993) <i>Derivation nominis:</i> Harting (1874, 1875) used the term 'Eem' to describe marine deposits in the subsurface near the Eem river. Zagwijn (1961) and Doppert et al. (1975) adopt the name for formal the lithostratigraphic unit
Description of the lithologic properties	<i>General lithology:</i> Gray calcareous sand (median 150–420 µm) bearing remains of marine mollusks, and gray calcareous clay bearing marine mollusks <i>Dominant lithology:</i> Gray calcareous sand (median 150–420 µm) bearing marine mollusks <i>Subordinate lithology:</i> Gray calcareous clay bearing remains of marine mollusks; marine shell beds <i>Sporadic lithology:</i> Diatomite (gyttja) <i>Lower boundary:</i> The Eem Formation usually rests conformably on glacial deposits of the Drente Formation from which it can easily be distinguished. Its base usually consists of sand, except in the glacial basins where thick beds of clay form the base of the unit. To the south of the maximum Saalian ice extent, the unit rests nonconformably on older sandy to clayey units <i>Upper boundary:</i> The nature of the upper boundary of the Eem Formation varies from sharp to diffuse and erosive to nonerosive over short distances. A general description of the upper boundary cannot be given <i>Other characteristic features:</i> Typical for the unit is the occurrence of marine mollusks, with diagnostic species (e.g., <i>Bittium reticulatum</i>, <i>Venerupis aurea</i> var. <i>senescens</i>, <i>Echinocyamus pusillus</i>, <i>Ostrea</i>) <i>Regional differential lithologic properties:</i> In the Saalian glacial basins, clay beds of >10 m thickness are present (>25 m in the replacing lectostratotype). Within the formation one unit of lower rank is discerned: ● Brown Bank Member (after Cameron et al., 1984; 1989; Rijdsdijk et al., 2005; Oele, 1971). This unit consists of (regressive) marine to lacustrine silty clay and fine sand of early Weichselian age. It occurs only in the present North Sea where it forms the top of the formation <i>Thickness:</i> The unit is typically around 10–15 m thick. In the glacial basins, thickness can be as much as 70 m. To the south of the Saalian glaciation, the unit is thin (1–10 m)
Stratotypes	Drillhole 25E0913 at Amsterdam Terminal, interval between 28.10 and 63.50 m below the surface; loose exemplary, replacing lectostratotype (Van Leeuwen et al., 2000) Drillhole 32B0119 near the Eem river, interval between 13.21 and 27.71 m below the surface; nominal, changing lectostratotype (Cleveringa et al., 2000; Doppert et al., 1975; Zagwijn, 1961) Drillhole P5-4 (P5-2 in Oele, 1971), interval between 2.75 and 6.0 m below the surface; loose exemplary regional hypostatotype for the Eem Formation, nominal holostratotype for the Brown Bank Member
Genesis	Marine, from transgressive at its base to regressive near the top. In the deeper parts of the southern North Sea, the unit grades into (glacial) lacustrine deposits
Relation to other (litho)stratigraphic units	Because the original 'Eem' stratotype also serves as the nominal stratotype for the Eemian stage, the lithostratigraphic Eem Formation is often interpreted chronostratigraphical. Also, the unit is often wrongly correlated to nonmarine units of Eemian age
Relation to earlier described and defined units	The unit comprises the Eem Formation as defined by Zagwijn (1961) and Doppert et al. (1975) and the former Brown Bank Formation (Cameron et al., 1984, 1989; Oele 1971) with the exception of: ● 'related' peat beds that now form part of the Woudenberg Formation ● predominantly coarse-grained fluvial deposits containing reworked marine shells, now part of the Kreftenheye Formation The formation was earlier defined by: ● Zagwijn WH (1961) Vegetation, climate and radiocarbon datings in the Late Pleistocene of the Netherlands. Part I. Eemian and Early Weichselian. <i>Mededelingen Geologische Stichting N.S.</i> 14: 15–45 ● Doppert JW Chr., Ruegg GHJ, van Staaldin CJ, Zagwijn WH, and Zandstra JG (1975) Formaties van het Kwartair en Boven-Tertiair in Nederland. In: Zagwijn WH and van Staaldin CJ (eds.), <i>Toelichting bij geologische overzichtskaarten van Nederland</i>, pp. 11–56. Haarlem: Rijks Geologische Dienst
Age	Upper Pleistocene (Eemian to Middle Weichselian)

Examples from the Quaternary Record

Splitting or Lumping? Scale and Hierarchy of Lithostratigraphic Units

When defining lithostratigraphic units from outcrops or from a single drillhole, some workers are inclined to identify as many units as possible. They like to split up the sedimentary record in many formal lithostratigraphic units. Their goal is to have a detailed local framework which often seems to serve a detailed scheme of climate-induced events (Van Huissteden et al., 1986; Zagwijn and Paepe, 1968). Others argue that those detailed local frameworks hamper communication and correlation on a higher level. These workers prefer to identify few formal lithostratigraphic units. They describe the internal lithologic variation within the lithostratigraphic units in terms of facies variation. In other words, they lump facies associations into lithostratigraphic units. Splitting or lumping is a matter of taste. Based on our mapping and modeling experiences, we prefer the latter. If one clearly identifies and describes the facies units within a given lithostratigraphic unit, communication and correlation is as easy at the local level as it is at higher scale levels. Further, a proliferation of names is inhibited.

As stated above, the formation is the central unit in lithostratigraphic classification. One of the main problems in applying lithostratigraphy in mapping is scale. In the past, many Quaternary geologists defined formations from outcrops or drillholes when working in a given area. Workers in other areas did the same. When mapping proceeded, it often appeared that they had defined the same unit, or parts of a unit that was defined elsewhere also. Figure 5 gives an example from glacial units in northern America (after Karrow, 1989). Karrow's figure suffices for communication and correlation in the Ohio–Ontario region. Things worsen, however, if the glacial units are correlated further away. This soon leads to a proliferation of names. The same happened in Great Britain where workers in the continental record defined many 'glaciogenic' and 'fluvial' formations. Bowen (1999a,b) attempted to clarify the nomenclatural jungle that had developed over the years, despite the efforts of the authors their classification does not always lead to clarification. In particular, lithostratigraphic

units of fluvial and glacial origin were 'grouped' together without an attempt to regroup them in order to get rid of the proliferation of names at the formation level. Bowen (1999b, p. 7) recognized the problem, but apparently he and his co-authors were not able to solve it at the time. McMillan (2005) clearly reduces the confusion in defining three glaciogenic groups (with many regional subgroups) and the Britannia Catchment Group with 24 regional subgroups. All the previously defined fluvial and glaciogenic lithostratigraphic units are maintained and placed into the subgroups. Although admirable and clearly a major clarification, this places the subgroup in the center of the lithostratigraphic classification. This does not really matter as long as one realizes that it deviates from the concepts of Hedberg (1976) and Salvador (1994).

In the Netherlands, a completely revised lithostratigraphic classification of the Tertiary and Quaternary was published in 2000 (available on the internet via www.dinoloket.nl), 2003 (Westerhoff et al., 2003), and 2005 (Rijsdijk et al., 2005). Here, all lithostratigraphic units were placed in four genetic categories (i.e., marine, fluvial, glacial, and local deposits). To maintain a clear link with the existing lithostratigraphic classification of the complete (predominantly sedimentary) record by Van Adrichem Boogaert and Kouwe (1993), the Upper Tertiary (Neogene) and Quaternary deposits were all placed in the Upper North Sea Group. The number of Quaternary formations defined by Doppert et al. (1975) slightly decreased. Many new formations contain several members.

Let us now consider the fluvial deposits of the Meuse in the new classification scheme. They are present in the southeastern part of the Netherlands (Figure 6). South of the Feldbiss Fault, Meuse deposits have been preserved in a well-documented flight of river terraces dating from the Pliocene to the Holocene (e.g., Felder and Bosch, 1989; Van den Berg, 1996; Van den Berg and van Hoof, 2001). In the subsiding area north of the fault, the Meuse deposits form a stacked unit with a terrace expression for the youngest units only (Saalian and younger). The Meuse deposits mainly consist of coarse sand and gravel. Locally, clay and loam beds are present. In South Limburg, the quartz content of the deposits increase with age (= height of the terraces). In McMillan's (2005) concept, the Meuse deposits would be placed together in a 'Meuse' Catchment Subgroup that would contain several formations. Westerhoff and Weerts (2003) and Westerhoff et al. (2003) chose to place the deposits into one formation, the Beegden Formation (named after its newly defined nominal, loose exemplary holotype; drillhole 58D0203 near the town of Beegden, Westerhoff and Weerts, 2003). No members are discerned in the thick stacked Beegden Formation deposits north of the Feldbiss fault, simply because they cannot be properly mapped. Consequently, the Meuse terrace deposits in South Limburg are included into the Beegden Formation as Members. River terraces are really morphostratigraphic units. To be valid as lithostratigraphic unit, each 'terrace' member needs to be described lithostratigraphically and it needs to have one or more stratotypes. Note that the Dutch approach maintains the formation as the central unit of a lithostratigraphic classification.

Another example from the revised lithostratigraphic scheme concerns the definition of Upper Pliocene and Lower Pleistocene fluvial deposits in the southern part of the Netherlands. This fluvial record results from the interplay of Rhine,

Figure 5 Correlation of independently defined glacial units in the Ohio–Ontario region (modified from Karrow PF (1989) Quaternary continental stratigraphy and neocatastrophism. *Quaternary Science Reviews* 8: 277–282). It is clear that the Boston, Caesar and Darby tills are a part of the Catfish Creek till unit. See text for further explanation.

Figure 6 Meuse deposits in the southeastern part of the Netherlands (a) and in South Limburg (b and c). See text for further explanation. Modified from Van den Berg MW (1996) *Fluvial Sequences of the Maas. A 10 Ma Record of Neotectonics and Climate Change at Various Time-Scales*, 181 pp. PhD Thesis, University Wageningen.

Meuse, and smaller rivers draining the central and northern part of Belgium. Lithostratigraphically, their deposits were defined by a mixture of litho-, chrono-, and biostratigraphical criteria. Pollen-defined (sub)stages, however, had a major control on the definition of lithostratigraphical units.

This lithostratigraphic subdivision was developed during the first half of the twentieth century. Based on differences in macro plant remains, which showed a climatic deterioration, a distinction was made between the Pliocene Reuver Clay and the Pleistocene Tegelen Clay (Reid and Reid, 1915). It is noteworthy that this (litho)stratigraphic assignment concerned only the clay deposits. The associated fluvial sand

deposits were not encountered in this subdivision. Subsequent research on mammal remains and pollen analysis confirmed that the Plio–Pleistocene transition could be placed in between the two clay deposits (Meijer, 1998; Zagwijn, 1998). Additional research on the sediment-petrographical composition showed a predominant stable heavy-mineral content (a.o. tourmaline, metamorphic minerals, staurolite, zircon) for the sand deposits below the Reuver Clay. The fluvial deposits found in between the Reuver and Tegelen Clay, however, showed a predominance of unstable heavy minerals (a.o. garnet, epidote, alterite/saussurite, hornblende). For a long time, it was thought that this major shift in heavy-mineral

Figure 7 Lithostratigraphy of the Upper Pliocene and early Pleistocene fluvial deposits in the SE Netherlands (Lower Rhine area). The chronostratigraphy is based on the work published by Zagwijn (1985, 1998). The now abandoned lithostratigraphy compared with Doppert et al. (1975) is shown in the middle column. At the right site, the revised lithostratigraphy (Weerts et al., 2003; Westerhoff, 2009) is given.

composition marked the biologically typified Plio–Pleistocene transition (Zonneveld, 1947a,b). The combined evidence was summarized in the lithostratigraphical scheme of Doppert et al. (1975). In this scheme, the Upper Pliocene and Lower Pleistocene fluvial deposits are assigned to three superimposed lithostratigraphic formations (Figure 7). (i) The lower unit comprises all Pliocene fluvial deposits and was assigned as Kieseloolite Formation. (ii) The middle unit is known as Tegelen Formation, a mixed Rhine–Meuse deposit with an assumed (pre)Tiglian to Early Eburonian age. (iii) The third unit is termed the Kedichem Formation. It overlies the Tegelen Formation and comprises all fluvial (mixed Rhine–Meuse and

Belgian rivers) and local deposits that postdate the Tiglian Stage.

New mapping results based on a large number of borehole and well-logging data obtained since 1975, have demonstrated that the interrelationship of the lithostratigraphic units discerned is much more complex than hitherto thought. Sediments with a lithological and petrographical composition similar to the Tegelen Formation were already deposited before the end of the Pliocene but also during post-Tiglian time (Boenigk, 1970, 1978, 2002; Boenigk and Frechen, 2006; Kemna, 2005; Kemna and Westerhoff, 2007). Deposits belonging to the Kedichem Formation comprise material derived

Figure 8 General section of a part of the Lutterzand exposures with the 'Beuningen Gravel Bed' and other desert pavements. Note that only in a part of the section there is one gravel bed present. In other parts, two or three beds are present while gravel beds are lacking in the northern part of the section. Modified from Wijmstra TA and Schreve-Brinkman EJ (1971) *The Lutterzand section, VI*. In: Van der Hammen T and Wijmstra TA (eds.) *Upper Quaternary of the Dinkel Valley. Mededelingen Rijks Geologische Dienst, Nieuwe Serie 22*: 87–99.

from two main and different source areas (i.e., the Rhine–Meuse river system and rivers that drained the central and northern part of Belgium) and interdigitate clearly with deposits of the Tegelen Formation. It is worthwhile mentioning that, according to the definition (cf. Doppert et al., 1975) and mainly determined by their supposed ages, all three of the formerly defined formations encompass river terrace deposits of the Meuse that occur in the southern part of Limburg.

Because of the reasons mentioned above, we have carried out a redefinition of the Upper Pliocene and Lower Pleistocene fluvial deposits in the southern part of the Netherlands (Ebbing et al., 2003; Weerts et al., 2003; Westerhoff, 2009; Westerhoff et al., 2003). The content as well as the concept behind the two previously defined Tegelen and Kedichem Formations have changed considerably and therefore we also have replaced the original names of these formations (Salvador, 1994; Walsh, 2005a). Instead, two new formations are introduced (Westerhoff, 2009):

- The Waalre Formation describes mixed Rhine–Meuse deposits formed during the late Pliocene and early Pleistocene. The deposits are dominated by unstable ('Rhine') heavy-mineral associations.
- The Stramproy Formation encompasses deposits that are mainly formed by rivers draining the central and northern part of Belgium. The heavy-mineral composition comprises dominantly a stable assemblage.

Both new formations occur next to each other and interdigitate repeatedly. The distinction between the two formations is primarily based on the differences in provenance and is macroscopically well observable in the field and in borehole

samples. Furthermore, both formations have a clear stratigraphical position as they are bounded by two easily mapable marker horizons. The lower marker horizon reflects the marked change in petrography between the pre-Rhine deposits of the Kieseloolite Formation (typified by stable heavy-mineral associations) and the (Alpine) Rhine deposits (typified by unstable heavy-mineral associations). The upper horizon is marked by the coarse-grained gravel-bearing base of the Sterksel Formation which represents a major unconformity that occurs in large parts of the depositional area.

Compared to the former Tegelen and Kedichem Formations, the lower and upper boundary of the Waalre and Stramproy Formations are not determined by pollen-defined substages (i.e., Reuverian, Early Eburonian) but by a clear lithostratigraphical position that is distinguished using easily mapped major changes in lithology.

The 'Bed' in a Lithostratigraphic Sense

As stated earlier, a bed in our view is used only to identify a well recognizable stratum (strata) that acts as a regional marker. Consequently, we advise limited use of the bed in a lithostratigraphic sense. A bed is typically less than 2 m thick. Traditionally, beds are recognized from outcrops. A widely used bed in the Quaternary of the Netherlands is the 'Beuningen Gravel bed' that was defined by Van der Hammen et al. (1967) and Van der Hammen (1971) in the Dinkel area (Figure 8). This bed represents a deflation level that by the authors was directly linked to a distinct chronostratigraphic level in the Upper Pleniglacial of the Weichselian (note the direct link of inferred age and lithostratigraphic unit). It consists of a few

Figure 9 Holocene fluvial and coastal plain deposits in an across section from the western Netherlands. In the upper part, details on lithology and sedimentary facies are shown. The lower section shows the lithostratigraphy at the formation level. Note the stratigraphic position of the Basal Peat Bed between older underlying deposits and the base of the Naaldwijk Formation. Reproduced from Weerts HJT, Westerhoff WE, Cleveringa P, Bierkens MFP, Veldkamp JG, and Rijdsdijk KF (2005) Quaternary geological mapping of the lowlands of the Netherlands, a 21st century perspective. *Quaternary International* 133–134: 159–178; modified from Van der Spek (1994).

centimeters-thin bed of coarse sand and fine gravel that is often seen in outcrops and encountered in drillholes in the eastern part of the Netherlands. Now if one studies schematic sections based on outcrops in the type area by [Wijmstra and Schreve-Brinkman \(1971\)](#) and [Wijmstra and Schalke \(1971\)](#), it is obvious that there are several deflation levels present in the area,

all represented by centimeter-thin coarse sand and gravel. In some sections three or four levels are present, while at other locations, none are found due to subsequent erosion ([Figure 8](#)). Should we now use this 'bed' as a formal lithostratigraphic unit? The Beuningen Gravel Bed is a facies unit; a centimeter-thin coarse-grained desert pavement. Given the

paleoclimatic conditions during the Weichselian pleniglacial in the Netherlands, those desert pavements can be expected at several levels. This was also recognized by Van Huissteden et al. (1986, p. 57), who represented the Beuningen Gravel Bed as diachronous in their schemes, but failed to dismiss it as a lithostratigraphic unit. When one does not have outcrops at his hand, it is impossible to say if one encounters the 'true' Beuningen Gravel Bed or just another local deflation level. So, (i) the unit does not represent a clear regional marker and (ii) it is impossible to map. Conclusion: The Beuningen Gravel Bed should be abolished as lithostratigraphic unit.

Another widely used bed in Dutch stratigraphy is de basal peat bed ('Basisveen' or basal peat bed). It represents the peat that underlies the clastic wedge of Holocene deposits in the coastal plain that formed as a result of the Holocene rising sea level. It has been described and used by many authors under slightly different names (e.g., see De Jong and Hageman, 1960, p. 649, 'Basisveen'; De Mulder and Bosch, 1982, p. 120, 'Lower Peat'; Hageman, 1969, p. 375, 'Lower Peat'; Vos and Van Heeringen, 1997, p. 21 'Basal Peat'; several 1:50 000 Geological Survey of the Netherlands map sheets and their explanatory annotations). It was used both as a formal and an informal unit, sometimes described as a member and sometimes as a bed. Weerts et al. (2003) defined and formally described the 'Basisveen Laag' (English: Basal Peat Bed) as a lithostratigraphic bed (see also Westerhoff et al., 2003, p. 351, 'Basisveen Laag'; Weerts et al., 2005, p. 166, 'Basal Peat Bed'). The Basal Peat Bed always consists of a few centimeters to 2–3 m thick peat bed that rests on top of pretransgressive deposits and it is always covered by Holocene transgressive clastic marine or tidal deposits of the Naaldwijk Formation (Figure 9). As such, the organic formation of Figure 3 might represent the bed. Note that its stratigraphic position is always clear, but that the unit is highly diachronous! Its occurrence is widespread. In our view, this unit clearly represents a lithostratigraphic bed because it (i) occurs at an unambiguous, important stratigraphic level and (ii) it can easily regionally be mapped.

Conclusion

In this article, we gave a brief outline of how to apply a lithostratigraphic approach on Quaternary deposits. A main starting point is the adage that lithostratigraphy is a tool for communication among Earth scientists themselves and users of geological information. It, therefore, needs to be applied with clear rules and definitions. Around the world there are many examples of confusing stratigraphic schemes which hamper the clarification of the Earth's history and moreover the practical use of geological information in applied geoscientific studies. Especially, the latter will benefit from clearly defined lithostratigraphic units that are capable to serve as carrier for sediment of layer properties in for example numerical modeling.

Acknowledgments

Jan Ebbing, Piet Cleveringa, and Foppe de Lang are thanked for the many encouraging discussions in the working group on

Lithostratigraphy of *The Geological Survey of the Netherlands*. We thank Aleid Bosch for checking the correct use of the Eem Formation example. Han Bruinenberg is thanked for drawing the figures.
